Cervico- thoracic spine	Damage to the cervical intumescence produces clinical signs that reflect damage to the grey mat- ter and brachial plexus ^b	i. No head signs ii. LMN ^c wing signs iii. UMN leg and vent signs unless brachial plexus lesion, only (ii)
Thoraco- lumbar spine	Damage to spine caudal to cervical intumescence* and cranial to lumbar intumescences reflects white matter lesions	i. No head or wing signs ii. UMN leg and vent signs iii. Possible kyphosis, spinal ± abdominal pain ^d iv. Variable loss of pain perception in limbs
Lumbosacral syndrome	A lesion in the lumbar intumescence° reflects damage to central gray matter and lumbosacral plexi'	i. No head or wing signs ii. LMN leg signs iii. LMN vent signs unless peripheral limb nerves only affected iv. Variable loss of sensa- tion in legs and vent

- a UMN = upper motor neuron. See Table 17.2.
- b Brachial plexus includes the pectoral, medianoulnar, bicipital, ventral propatagial, axillary and radial peripheral nerves.
- c LMN = lower motor neuron. See Table 17.2.
- d A space-occupying mass within the kidney or pelvic canal may place pressure on lumbosacral plexus and its ischiatic nerve, mimicking lumbosacral syndrome.
- e Lumbar intumescence encompasses lumbar, sacral and pudendal plexi.
- f Lumbosacral plexi includes the femoral, obturator, ischiatic, pudendal, pelvic and coccygeal peripheral nerves.

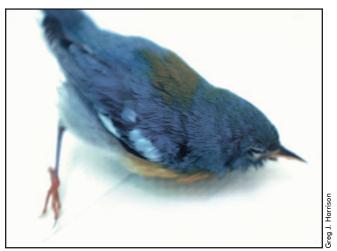

Fig 17.24 | A palm warbler (Dendroica palmarum) with pesticide toxicosis demonstrating incoordination.

Fig 17.26 | A cockatiel (Nymphicus hollandicus) with a spinal lesion of unknown etiology demonstrates a posture often seen with paraparesis.

Treatment

- 1. Specific treatment of the underlying etiology.
- 2. Skin care for recumbent birds or those that are dragging their limbs.
- 3. Physiotherapy.
- 4. Supportive care if unable to eat and drink.

DIFFERENTIAL DIAGNOSIS OF SPINAL AND NEUROMUSCULAR **DISEASE** (Table 17.6)

Degenerative

Psittacine Focal Symmetrical Poliomyelomalacia

This lesion has been documented in 15 adult birds in Australia, including five superb parrots, two budgerigars and one lovebird (Agapornis sp), all of which were from aviaries.53 In caged birds, there was a history of one or more birds suddenly becoming uncoordinated, having difficulty perching, followed by posterior paralysis. Some birds could still fly. Others became tetraplegic within 2 or 3 days.53

Fig 17.25 | An African grey parrot (Psittacus erithacus) with suspected Sarcocystis infection of the central nervous system exhibits torticollis and bilateral clenched claws.

Table 17.6 | Differential Diagnosis of Spinal and **Neuromuscular Disease**

Mechanism of Disease	Specific Diseases
Degenerative	i. Psittacine focal symmetrical Poliomyelomalacia ii. Lysosomal storage disease - Gangliosidosis iii. Avian vacuolar myelinopathy iv. Lafora
Neoplastic	i. Abdominal neoplasia - ovarian pathology/renal masses
Nutritional	i. Vitamin E deficiency ii. Thiamine (vitamin B ₁) deficiency iii. Riboflavin (vitamin B ₂) deficiency iv. Pyridoxine (vitamin B ₆) deficiency
Inflammatory	i. Viral - Proventricular dilatation disease/Marek's disease /Avian paramyxovirus type 1 (Newcastle disease)/Polioencephalomyelitis of rainbow lorikeets/Borna/Eastern and western equine encephalitis/West Nile virus/Picornavirus (duck viral hepatitis) ii. Fungal - Aspergillus spp.
Toxicity	i. Lead ii. Zinc iii. Tick Paralysis iv. Organophosphates, carbamates and insecticides v. Plant toxins vi. Botulism
Trauma	i. Peripheral nerve trauma ii. Spinal trauma
Vascular	i. Fibrocartilaginous embolic myelopathy

Lysosomal Storage Disease

Gangliosidoses are most commonly caused by deficient activity in one of the two enzymes necessary for ganglioside catabolism.18 Specifically, an inherited defect in ßgalactosidase is associated with GM₁ gangliosidosis and a similar defect affecting the activity of ß-hexosaminidases is associated with GM₂ gangliosidosis. 18 The enzymatic defects lead to an accumulation of GM, or GM, respectively, within the neurons of the central and peripheral nervous system. Two related juvenile emus have been reported with severe, progressive, eventually fatal intraneuronal gangliosidosis.18 Analysis of affected brain tissue demonstrated significant elevations in total gangliosides with low levels of lymphocyte ß-galactosidase.18

Avian Vacuolar Myelinopathy (AVM)

AVM has been diagnosed in wild birds in the southeastern USA. It was first documented in bald eagles (*Haliaeetus leucocephalus*) in 1994 and also has been found in American coots (*Fulica americana*). ¹¹⁵ Bald eagles are frequently found dead, but have been noted to have difficulty flying and can crash into or overfly perches. Affected coots appear to fly or are wobbly in flight; they are uncoordinated on land and may swim in circles or on their backs. ⁷¹ On neurologic examination, the majority of coots have been documented with ataxia, decreased withdrawal reflexes, proprioceptive deficits and decreased vent responses. ⁷¹ Other signs seen in less than half of examined coots include beak and tongue weakness, head tremors, absent pupillary light responses, anisocoria, apparent blindness and nystagmus. ⁷¹

Birds that die have no gross lesions of the nervous system, and some coots have been documented to recover from this disorder with supportive care. Histologically, the disease is characterized by diffuse, spongy degeneration throughout the white matter of the CNS with the optic tectum most severely affected. The etiology remains unknown.

Lafora's Disease

Lafora's disease is a presumed inherited defect of carbohydrate metabolism first documented in humans. ¹⁰³ This disturbance of the carbohydrate metabolism causes the formation of typical Lafora-bodies, which consist of polysaccharide complexes. Similar changes have recently been described in two cockatiels (*Nymphicus bollandicus*). ¹⁵

Neoplasia

Primary spinal neoplasia is rare in birds. Compressive peripheral nerve trauma generally occurs secondary to an expanding mass that applies pressure to the nerve, because the pelvic nerves pass through the renal parenchyma.¹⁵

Nutritional

Vitamin E/Selenium Deficiency

Clinical signs associated with vitamin E and selenium deficiencies include tremors, ataxia, incoordination, reluctance to walk and recumbency.¹⁵ This deficiency has been incriminated as the etiology of cockatiel paralysis syndrome. This condition appears to occur most frequently in lutino cockatiels, but similar syndromes have been reported in a variety of other species including blue and gold macaws, eclectus parrots and African grey parrots.¹⁵ Supplementation with injectable and oral vitamin E is the recommended treatment, however, the patient may or may not respond, depending on the severity of damage.

Thiamine (Vitamin B₁) Deficiency

Clinical signs of thiamine deficiency include ataxia, ascending paralysis and opisthotonus.¹⁵ A response to treatment provides a presumptive diagnosis, as affected birds generally respond within hours of oral or parenteral administration of vitamin B₁.¹⁵

Riboflavin (Vitamin B₂) Deficiency

Birds with this deficiency have weakness, atrophy of the leg muscles and are seen to walk on their hocks with their toes curled inward, although this does not always happen because death may occur first. ^{15,118} The condition has occasionally occurred in chickens, but since riboflavin has been added to poultry feed it has become quite rare. ¹¹⁸ Leg and wing paralysis has been reported in racing pigeons with this disorder. ¹¹⁸ The deficiency causes a demyelinating peripheral neuritis. Treatment involves administration of oral or parenteral riboflavin and diet correction.

Pyridoxine (Vitamin B₆) Deficiency

Deficiency of this vitamin causes characteristic jerky, nervous walking, progressing to running and flapping the wings.¹⁵

Inflammatory

Viral Disease

Proventricular Dilation Disease (PDD) has been reported to cause peripheral (sciatic, brachial and vagal) neuritis in psittacine birds.¹⁷

Marek's Disease Virus (MDV) in chickens is caused by an oncogenic herpesvirus and is characterized by lymphomas and paralysis. 43 Paralysis associated with MDV infection has usually been attributed to peripheral nerve lesions because gross enlargement of nerves with lymphoid infiltrates is a common feature of MD, and CNS damage has not been found consistently in paralyzed birds.43 The onset of both lymphomas and paralysis usually occurs 4 to 12 weeks after infection with MDV.43 A paralytic syndrome involving the brain also is induced by MDV and is now designated transient paralysis (TP).43 Clinically, TP is characterized by the development of a flaccid paralysis 8 to 12 days after infection with an oncogenic MDV. This initially affects neck muscles and later tends to become generalized. 43 Most birds with TP recover completely within 24 to 48 hours, although a few birds that become severely affected may die within the same period of time. 43 A more acute and fatal form of TP has recently been described in young chickens. 123

Once known as fowl paralysis and range paralysis, it was considered that gross enlargements of the peripheral nerves were a pathognomic lesion. However, gross enlargement of peripheral nerves also can be induced by reticuloendotheliosis virus (REV). Both REV and

subgroup J avian leucosis virus can induce lymphoid infiltrations in peripheral nerves, indicating that additional criteria may be needed for confirmation of etiology.7

Avian Paramyxovirus Type 1 (Newcastle Disease) is a variable disease with different susceptibilities between avian orders.8 The disease is produced following infection and varies with virus pathotype; other factors include the species, age, immune status, general health of the bird and environmental conditions.8 Clinical neurologic findings in affected birds include ataxia, torticollis, opisthotonus, head shaking and tremors, head tilt, leg paralysis progressing to lateral recumbency and blindness.8 Some birds may survive for up to 18 months after developing CNS signs, but the CNS signs do not regress before death or euthanasia.8 Definitive diagnosis requires virus isolation, demonstration of the viral antigen, or rising specific antibody titers.8 A titer of 1:8 is usually considered evidence of exposure to this virus, and in unvaccinated birds when coupled with clinical signs is considered strong diagnostic evidence of infection.8

Suspected Viral Polioencephalomyelitis of Rainbow Lorikeets (Trichoglossus haematodus) has been documented in 35 rainbow lorikeets in Australia.53 It affects adults at any time of the year and usually causes an inability to fly or perch. The birds are commonly alert and will eat, but are characteristically affected with clenched claws.53 The cerebellum was affected in about half of the birds, and the lesions were largely restricted to the central cerebellar white matter and involved the roof nuclei.

Borna Disease Virus has been documented to cause a paretic condition in young ostriches in Israel.⁴ Birds between 14 and 42 days old were affected. In a small number of cases, clinical signs of incoordination were seen 1 to 3 days before paresis supervened. At this stage of the disease, the birds could stand and move with difficulty if given external support.4 Mortality can be remarkably high. About 1% of the ostriches seemed to recover if they were given intensive supportive care, however, they relapsed several months later.4

Eastern and Western Equine Encephalitis infections can cause weakness and paralysis of the legs.⁹⁶

Picornavirus (Duck Viral Hepatitis) has been associated with neurologic signs in Galliformes, Anseriformes and Columbiformes of less than 28 days of age.15 Clinical signs documented include depression, ataxia, paresis or paralysis, and severe but fine head and neck tremors.

West Nile Virus has been documented to cause paresis and paralysis in many avian species.⁷⁸

Fungal Disease^{21,22,46,102}

Toxicity

Lead

Lead toxicity, one of the most commonly recognized poisonings of companion and free-ranging birds, is a common cause of neurologic abnormalities and can be fatal. 92 Peripheral neuropathies caused by lead intoxication have been reported, but it is more common to see central nervous system abnormalities. 92 Various sources of lead have been documented, but the source of lead in any specific poisoning often remains difficult to determine. A classic source of lead exposure for birds is ingesting lead shot from the bottom of lakes in heavily hunted areas.92 The combination of the grinding action of the ventriculus and its low pH (2.0-3.5) acts to solubilize ingested shot.92 Raptors may eat carcasses containing lead shot and become intoxicated.92 Inhalation of fumes from leaded gasoline is another possible route of exposure.92 Lead poisoning as a result of lead shot embedded in soft tissues is rare because of the avascular fibrous tissue that develops around these foreign bodies.92

Clinically, lead toxicosis may be an acute or chronic problem, with clinical signs dependent on the amount and surface area of lead ingested. 92 Clinical signs in birds include behavioral changes, lethargy, anorexia, vomiting, diarrhea, ataxia, limb paresis or paralysis, seizures, anemia and emaciation.92 Death may occur within 48 hours after the first appearance of clinical signs.92

Whole, unclotted blood is the sample of choice for determining lead concentrations because 90% of circulating lead is contained within RBCs. 92 Concentrations of $>20 \mu g/dl$ lead in whole blood are suggestive of lead intoxication in psittacine birds, and concentrations >40 to 60 μg/dl are diagnostic of lead toxicosis.92

Zinc⁷³

See Intracranial Disease above.

Tick Paralysis

Tick paralysis is a disease caused by neurotoxins associated with 60 species of hard and soft ticks in 10 genera.76 Generally, the disease is considered a motor polyneuropathy characterized by a progressive, ascending, flaccid motor paralysis. Clinical signs include ataxia, paresis, paralysis, areflexia, hypotonus and respiratory failure.⁷⁶ Death is common if the tick is not removed. 76 The toxin is associated with the female tick's salivary glands and is probably secreted during feeding.76 Ixodes brunneus has been associated with tick paralysis in birds.⁷⁶ All three stages of the tick feed exclusively on birds, particularly passerines and group-feeding species; at least 64 species of birds are known to be hosts for this tick.76 Adult females are found on adult birds primarily in the colder

months of the year, with larvae and nymphs occasionally present at the same time, causing clinical signs during winter months.⁷⁶

A definitive diagnosis of tick paralysis can be based only on dramatic clinical improvement and recovery of the host, usually within 24 to 72 hours following removal of the tick.

Organophosphates and Carbamates

Organophosphorus-induced delayed neurotoxicity (OPIDN) is a neurologic condition characterized clinically by the delayed onset of a progressively developing hindlimb ataxia and paralysis. 90,116 Two categories of OPIDN — Type I and Type II — have been identified, 116 and differ from each other in the length of the delay period prior to onset of symptoms, the type of resultant clinical signs and the extent of central nervous system involvement. Type I OPIDN has a longer delay period (typically 10-21 days) and affects only the spinal cord and brainstem, whereas type II OPIDN has a shorter delay period (4-7 days) and results in additional degeneration in the midbrain and forebrain. Widespread neuropathology follows both oral and injectable forms of the compounds. 116

Plant Toxins

*Nerium oleander*² (See Chapter 31, Implications of Toxic Substances in Clinical Disorders.

Botulism (Limberneck)

Botulism in birds is usually the result of ingestion of the exotoxin of *Clostridium botulinum* type C. Occasionally *C. botulinum* type A and type E are involved.¹⁵ This is an uncommon problem in companion birds but frequent in waterfowl.^{15,45,70} The classic sign is limberneck resulting

from paralysis of the cervical muscles.¹⁵ Most birds exhibit hindlimb paresis first, which progresses to paralysis of the wings, followed by loss of control of the neck and head in the terminal stages.¹⁵ Species' susceptibility and clinical manifestations vary, as has been evidenced in rehabilitation facility outbreaks.

Trauma

Spine Trauma/Peripheral Nerve Trauma

Trauma is fairly common in free-ranging as well as companion and aviary birds. The consequences, diagnosis and management of these traumas have been well discussed in other texts.¹⁵

Vascular

Fibrocartilaginous Embolization

Emboli may involve vessels of the spinal cord, leptomeninges or both. Fibrocartilaginous embolism (FCE) and ischemic myelopathy have been reported in several 15-week-old tom turkeys with peracute onsets of paresis and ataxia. Recovery was noted in some affected birds suspected to have this disease, but cartilaginous emboli were found in the spinal cord vasculature accompanying myelomalacia in three turkeys that did not recover. The articular cartilage of the vertebral body endplates are suggested to be the source of the emboli, as there were articular cartilage defects found in the affected birds. There is no known treatment in any species and diagnosis is by exclusion. Recovery is possible in some cases, but supportive care would be necessary.

Evaluating and Treating the

Reproductive System

HEATHER L. BOWLES, DVM, Dipl ABVP-Avian, Certified in Veterinary Acupuncture (Chi Institute)

Reproductive Embryology, Anatomy and Physiology

FORMATION OF THE AVIAN GONADS AND REPRODUCTIVE ANATOMY

The avian gonads arise from more than one embryonic source. The medulla or core arises from the mesonephric ducts. The outer cortex arises from a thickening of peritoneum along the root of the dorsal mesentery within the primitive gonadal ridge. Mesodermal germ cells that arise from yolk-sac endoderm migrate into this gonadal ridge, forming the ovary. The cells are initially distributed equally to both sides. In the hen, these germ cells are then preferentially distributed to the left side, and migrate from the right to the left side as well.58 Some avian species do in fact have 2 ovaries, including the brown kiwi and several raptor species. Sexual differentiation begins by day 5 in passerines and domestic fowl and by day 11 in raptor species. Differentiation of the ovary is characterized by development of the cortex, while the medulla develops into the testis.30,58

As the embryo develops, the germ cells undergo three phases of oogenesis. During the first phase, the oogonia actively divide for a defined time period and then stop at the first prophase of the first maturation division. During the second phase, the germ cells grow in size to become primary oocytes. This occurs approximately at the time of hatch in domestic fowl. During the third phase, oocytes complete the first maturation division to

become secondary oocytes. Completion of the second maturation period results in an ovum.30,34,53,58

The ovarian medulla consists of blood vessels arranged in irregular vascular zones, interstitial cells, autonomic nerve fibers and smooth muscle. The ova are located peripherally in the cortex of the ovary. The ovarian surface is covered by parietal peritoneum with an underlying layer of dense connective tissue, the tunica albuginea. The ovary is located just caudal to the adrenal gland, near the tip of the cranial division of the kidney. It lies deep to the abdominal air sac, which forms an ovulation pocket near the time of lay. This pocket is thought to help receive the ovulated ovum with its yolk into the oviductal opening. The pocket is suspended by a dorsal mesentery, the mesovarium. Vascular supply to the ovary is through the cranial renal artery, which has several short branches. There are often two ovarian veins that drain blood directly into the caudal vena cava. The ovary has a roughened, granular appearance due to follicular development. As the hen becomes sexually active, the follicles begin to grow in a hierarchal pattern. 30,34,53,58

The oviduct enlarges to occupy the dorsal aspect of the left intestinal peritoneal portion of the coelomic cavity. Seasonal growth and differentiation of the reproductive tract is under hormonal control. In a mature hen that is not reproductively active, the ovary and oviduct appear similar to that of a juvenile bird: small with no active follicles. The oviduct develops from a thickening in the peritoneal epithelium between the degenerating pronephric ducts and the first mesonephric tubules. These thickenings invaginate to form a tubular structure. This process occurs bilaterally and symmetrically in both sexes, but regression and disappearance of the ducts occurs in the cock and a relative regression of the right duct occurs in the hen. A right oviduct may be present in some raptors. The opening of the oviductal lumen into the cloaca often appears near the time of production of the first egg. 30,34,53,58

There is a period of time during fetal development when the testes are ambisexual due to extensive covering with a cortical crust. These cortical remnants normally disappear prior to hatch; however, they may remain and further complicate visual sex identification. The seminiferous tubules differentiate in the medullary portion of the gonad. The ductus deferens develops from the mesonephric duct, while the epididymis arises from the mesonephros. The epididymis and ductus deferens initially develop in both sexes, as does the oviduct. The male tubular structures normally regress in the female. However, they have been reported to persist in some passerines and domestic fowl, but are significantly smaller than the oviduct. 23,35,58

AVIAN REPRODUCTIVE PHYSIOLOGY

Avian reproduction is guided by seasonal physiologic controls such as favorable climate, low predation risk, social interaction, and food and nest site availability. Internal physiologic processes work in combination with external factors to promote gonadal development. This annual cycle involves integration between environmental, physiologic and behavioral conditions. Biologic clocks control the release of hormones and other chemicals that regulate metabolism, reproduction and behavior. Photoperiod plays a key role in this system using environmental light, which stimulates neural receptors, and clock information from an internal circadian cycle. This allows the bird to measure day length. In most of our Neotropical psittacine species, birds normally start to nest when the rains begin, when food is the most available. In temperate zone species, reproduction is stimulated by photoperiod. The lengthening day in early spring stimulates gonadal development. Warmer temperature, rainfall and behavioral displays fine-tune the physiologic events of breeding and the resulting increased secretion of sex hormones. 23,47,55,58

There is strong evidence that the pineal gland (hypophysis cerebri) is largely responsible for photoperiodic control. However, unlike reptiles, the avian pineal gland does not have primary light receptors, but they do have photoreceptors like cells in the brain and retinae. Birds do not monitor day length visually, but rather by means of special receptors in the hypothalamus. After direct stimulation of the photoreceptors, neurosecretory cells in the hypothalamus induce the release of neurohormones in the median eminence (neural portion) of the epiphysis (pituitary), which is linked to the midbrain. These neurohormones are then carried via the bloodstream to the anterior pituitary gland, inducing the synthesis and subsequent release of luteinizing hormone (LH) and follicle-stimulating hormone (FSH). Luteinizing hormone stimulates gonadal activity and in combination with FSH stimulates ovarian development and testicular spermatogenises. 23,37,54,55,70 See Ed. Note on page 522.

Each circadian cycle includes a limited time period of each day during which photoreceptors are particularly sensitive to light. This stimulates a series of physiologic reactions. As daylight length increases each year, so does the opportunity for light to stimulate these receptors during this limited time period. In addition, the length of time these receptors are affected increases with increasing daylight length (see Chapter 19, Endocrine Considerations). 23,37,55,70

During the late summer after breeding season has ended, the shortened daylight length stimulates the main molt. Gonadal hormones and tissue size decreases dramatically. Although the days are still relatively long, there is a photorefractory period that does not stimulate gonadal hormone release and tissue growth. This photorefractory period is best developed in migratory temperate zone species and is weak to absent in most tropical zone species. This may represent an adaptation for scheduling a major molt and preparation for migration by terminating reproductive activity while days are still long. The shorter days of winter inhibit gonadal growth. This is necessary to restore photosensitivity during the spring, as gonadal tissue will not grow in response to increasing day length unless there has been a prior period of short daylight length.^{34,35,58}

Birds have developed several mechanisms to reduce body weight, thereby conserving energy expended during flight. The reproductive tract (ovary, oviduct, testes and ductus deferens) is greatly reduced in size during the non-breeding season, and eggs are laid and incubated externally.^{34,35,58}

Physiology of the Female

When reproductively active, the ovary enlarges and follicles form in a hierarchal manner. The primary or F1 follicle is the largest and first in line to be ovulated. There are several smaller follicles on the ovarian surface as well. A stalk that contains smooth muscle with a blood and nerve supply suspends each large follicle. 30,34,49,58 Gonadotropin secretion causes follicles to develop on the ovary in a hierarchal manner. As the breeding season approaches, follicles undergo a period of rapid development and growth. There is deposition of yolk protein and lipid from the liver; gonadotropins and steroid hormones regulate this. The primary oocyte is surrounded by six layers of tissues: the oocyte plasma membrane, perivitelline membrane, granulosa cells, basal lamina, and the theca interna and externa. These tissues have an endocrine role, providing communication between the ovary and oviduct with passage of each ovum. The nerve supply is both adrenergic and cholinergic. Ovulation occurs under the influence of several hormonal factors. Meiotic or reduction division occurs approximately 2 hours preovulation, while the primary oocyte is still within the follicle. This yields a secondary oocyte and first polar body, each with a haploid number of chromosomes. Most birds have a meridional band or stigma on large preovulatory follicles. This is where the oocyte breaks through the follicular wall during ovulation. 30,34,58

Ovulation occurs at a relatively fixed time period after oviposition under several physiologic, neural and hormonal controls. Determinant layers such as budgerigars and crows lay a fixed number of eggs, while indeterminate layers such as domestic fowl and Japanese quail replace eggs that are lost. Continuous breeders lay throughout the year. A rate of lay is the number of eggs laid in a given time period. A sequence is a number of eggs laid on successive days, separated by pause days. A clutch is a number of eggs laid during a sequence. A longer sequence is associated with a shorter oviposition/ovulation cycle. ^{30,31,34,52}

During the non-breeding season, ovarian follicles normally undergo atresia. Atresia is a process of regression and resorption of a follicle. Two types of atresia have been described: bursting and invasion. Bursting atresia occurs when the follicular wall ruptures and the yolk is released into the coelomic cavity where it is usually absorbed without any harm to the bird. Invasion atresia involves granulosa and thecal cells invading the ovum and subsequent in situ yolk absorption. Early atresia is noted when a vesicular lesion appears on the follicular surface. This vesicular formation progresses until the entire follicle is covered. As the largest F1 follicle is absorbed, the other smaller follicles will progress in a similar manner. Small follicles may be covered with connective tissue, occasionally leaving a scar-like area. Large follicles may undergo cystic degeneration. If ovulation ceases suddenly, as may occur during trauma or stress, developing follicles may become hemorrhagic, resulting in regression of the developing follicles. Aflatoxicosis also may cause follicular atresia. Aging hens may exhibit permanent ovarian involution, which is believed to be a normal physiologic process.30,31,34,73

Knowledge of the oviduct and its different anatomic regions is important in discerning pathologic conditions of the oviduct and developing egg. The oviduct is divided into five parts: the infundibulum, magnum, isthmus, uterus or shell gland, and vagina. A mucosal layer of ciliated epithelium with unicellular mucous glands or goblet cells lines the wall of the oviduct. The submucosa has mucosal folds that vary in height, thickness and tubular glands. The muscular layer has an inner layer of circular smooth muscle and an outer layer of longitudinal smooth muscle. 30,31,34,73

The infundibulum is divided into the proximal funnel portion and a distal tubular portion. The funnel portion is where fertilization occurs. It has a thin wall with low mucosal folds. This portion surrounds and engulfs the ovum during ovulation. At the beginning and end of the ovulatory cycle, the oviduct and ovary may not be synchronized, resulting in ectopic ovulation also referred to as internal laying. This yolk and ovum may be resorbed without incident or may lead to coelomitis. The exact mechanism by which coelomitis occurs after ectopic

ovulation is not well understood. 17,30,31,34,73

The tubular portion of the infundibulum is thicker, with taller branching folds. Underneath these folds are branched, convoluted tubular glands that produce the chalaza, which are fibrous bands that suspend the yolk within the egg. A thin, dense layer of albumin is added to surround the yolk. In some species, sperm host glands maintain sperm for fertilization for a variable time period and are located within this portion of the infundibulum.^{17,30,31,34,73}

Large mucosal folds that result from numerous tubular glands distinguish the magnum histologically. It is the longest portion of the oviduct. The majority of albumin as well as sodium, magnesium and calcium are added to the egg by these glands. The release of albumin may be controlled by mechanical, neural and endocrine factors. ^{17,30,31,34,73}

The isthmus follows and, in domestic fowl, is clearly delineated from the magnum by a narrow translucent band. This band is not present in psittacines. The isthmus is relatively short and the mucosal folds are less prominent. The tubular glands are unique in that they produce sulfur-containing proteins. These proteins are incorporated into the shell membranes that are produced in the isthmus. A small amount of albumin is added to the developing egg. Calcification is initiated in the isthmus. 17,30,31,34,73

During passage of the egg through the oviduct, the majority of the time is spent in the uterus, or shell gland. There are two portions: a short, narrow region which the egg traverses rapidly, and a pouch-like region where the egg spends the majority of the time. The mucosal lining is characterized by a large number of leaf-like lamellar folds that press against the surface of the egg. This increases the surface area to improve efficiency of calcification and plumping. "Plumping," a process in which a large amount of water and solutes are added to the egg relatively quickly, occurs in the proximal short, narrow region of the oviduct. It is in the pouch-like region that calcification of the shell is completed.^{17,19,30,31,34,75}

The vagina is separated from the uterus by the uterovaginal sphincter. In most species the egg passes rapidly through the vagina to exit into the urodeum. However, in some species the egg may remain for a longer time period to allow for hardening of the shell. There are sperm host glands at the uterovaginal sphincter for sperm storage. Sperm from multiple male birds may be stored and remain viable for long time periods. This may be up to several months in the turkey. This allows for the possibility of insemination of different ova of a single clutch by different males. 17,19,30,31,34,58,73

Physiology of the Male

The testes are paired, ellipsoid- to bean-shaped organs that lie near the cranial pole of the kidney. The surface is covered with a fibrous tunic, the tunica albuginea. Each testicle is suspended by a short mesentery or mesorchium that protrudes into the intestinal peritoneal cavity and is partially surrounded medially by the abdominal air sac. The testes change in size and color in response to hormonal fluctuations that influence sexual activity. The inactive testicles are often white to yellow due to accumulation of lipid in the interstitial cells. In some species, the inactive testicles are black due to a large number of melanocytes. Active testicles are significantly larger and paler due to the increased volume in the seminiferous tubules. The increased size is a result of increased length and diameter of the seminiferous tubules, and numbers of Leydig or interstitial cells. Generally speaking, the increase in testicular size is a result of increasing serum concentrations of FSH and LH. These physiologic processes occur during the nuptial or culmination phase of the reproductive cycle. 35,38,52,73 (Ed. Note: These results bave not been verified since FSH was purified. Prior to the early 1990s, FSH was contaminated with LH [Etches, R, University of Guelph, 2003]).

Birds do not have septa that divide the testicles and there are no mediastinal testes. Unlike mammals, the seminiferous tubules anastomose with each other. Each seminiferous tubule is composed of a lining of spermatogonia and sustentacular or Sertoli cells. The spermatogonia divide to form primary, then secondary spermatocytes. As these spermatocytes progress toward the lumen, they undergo a maturation process to become spermatids, which then mature into spermatozoa or sperm. This maturation process proceeds with the head of each sperm embedded in the sustentacular cells. The sustentacular cells extend the width of the epithelium to provide support for the developing spermatozoa. They are phagocytic and also may produce steroid hormones and bind testosterone. 35,38,58

The spermatozoa detach from the Sertoli cells and travel down the seminiferous tubules when mature. In most species, these tubules converge into a smaller number of short, straight tubules that continue as the rete testes. The rete testes is a meshwork of tubules embedded in connective tissue, located dorsomedially to each testicle, adjacent to the epididymis. Both the rete testes and straight tubules are lined by sustentacular cells.^{35,38,58}

The Leydig, or interstitial, cells are located between the seminiferous tubules. They are light-colored and stain eosinophilic with hematoxylin-eosin stain because of the large concentration of smooth endoplasmic reticulum and cholesterol. The smooth endoplasmic reticulum is

involved in the conversion of cholesterol to steroid hormones, with testosterone and androstenedione being the major androgens. These hormones stimulate the secondary sex characteristics, including courtship, coloration, song, and the development and maturation of the tubules, particularly the ductus deferens. 35,38,58

The epididymis of the bird is concealed due to its dorso-medial location on the testicle and its small size compared to mammals. It is not divided into a head, body and tail, but is composed of several efferent ductules that drain the rete testes and straight tubules. Several efferent ductules drain into the main epididymal duct along its length. The epididymal duct is relatively short and straight, and is lined by non-ciliated pseudostratified columnar epithelium. The epithelium is secretory and provides some of the seminal fluid. Sperm may be stored in the epididymis or in the seminal glomus of more seasonal birds. Some species have an appendix epididymis that extends cranially into the adrenal gland. The efferent ductules of this tissue may secrete androgens following castration. 35,38,58

The epididymis continues distally as the ductus deferens. The ductus deferens is closely associated with the ureter in the dorsomedial coelom. In passerines, each ductus elongates distally during the culmination phase of the reproductive cycle to form the cloacal promontory, which can project into the cloaca. This protrusion gives the male external cloaca a pillar-like prominence compared to a rounded profile in females; therefore, it can be used for sex determination during the breeding season. Birds with a seminal glomus use it as the main storage site for sperm. The ductus is composed of nonciliated pseudostratified squamous epithelium and has less secretory function when compared with the epididymis. There are no accessory sex glands in birds. 35,38,58

Avian semen is derived in part from the sustentacular cells and epithelial cells that line the reproductive tract. Lymph-like fluid is produced from lymphatic folds in the floor of the proctodeum. This fluid appears to be harmful to spermatozoa because of the presence of clotting factors and high concentrations of chlorine and calcium. Avian spermatozoa are either complex or simple. Complex sperm is found in passerines and simple sperm in other species. Similar to mammals, each spermatozoon is composed of an acrosome, head and tail. In simple spermatozoa, the acrosome is attached to the head only at its most rostral point. The head is long and slender, and the tail is long and moves in an undulating manner. In complex sperm, the entire sperm is spiral in appearance and moves by rotating along its longitudinal axis.^{35,38,58}

See Chapter 14, Evaluating and Treating the Gastrointestinal System for a discussion of the cloaca. The vent may be either a circular opening as in psittacines or a transverse slit as in Galliformes. The sphincter muscle surrounds the opening and has an outer circular and an inner transverse striated muscle layer. In addition, there is a transverse muscle originating on the pelvic bone and/or caudal vertebrae that interdigitates with the sphincter muscle surrounding the vent. Upon contraction of this transverse muscle, the vent is pulled ventrocranially, which is important during coitus. This muscular action allows the cloaca in the male bird to be directed over the female's cloaca. The levator muscle originates on the ventral tailhead and inserts ventrally onto the vent and/or the phallus. This muscle pulls the vent caudally after copulation and defecation. 15,36,73

The phallus may be intromittent as in ratites and Anseriformes, non-intromittent as in Galliformes, or absent as in psittacines and passerines. The intromittent phallus may be found in two forms: one form lacks a ventral cavity, and is found in ostriches, kiwis and tinamous; the other form has a cavity and is found in emus, rheas, cassowaries and Anseriformes. The former type of phallus consists of paired fibrolymphatic bodies with a dorsal sulcus to deliver semen. It lies on the floor of the cloaca and partially everts during micturition and defecation. Tumescence occurs by increased lymphatic flow and stasis into an elastic vascular body within the distal end of the phallus. Those phalluses with a ventral cavity also are located on the cloacal floor, but are enclosed in a sac or cavity. The proximal portion stays within the cavity and does not become engorged, while the distal portion everts when engorged with lymphatic fluid. 15,36,73

The non-intromittent phallus, as found in domestic fowl, is located on the floor near the lip of the vent. It consists of a median and two lateral phallic bodies. Lateral to the phallic bodies are lymphatic folds located on the ventrolateral floor of the proctodeum. A lymphatic meshwork connects these folds and phallic bodies. Tumescence is a result of lymphatic flow through these structures. The lymphatic folds and lateral phallic bodies accumulate a greater amount of fluid than the median phallic body, resulting in eversion of the phallus and creating a groove for delivery of semen. The phallus contacts the everted oviductal opening where semen is deposited. 15,36,73

Reproductive Disorders

Avian reproductive disorders are a result of complex combinations of hormonal, physiologic and behavioral actions reacting to photoperiods, food availability and availability of nest sites.^{30,70} Environmental influences in captivity may result in the induction of reproductive and hormonal activity in several ways. Artificial lighting may

interfere with the normal photoperiod and annual light cycles, resulting in abnormal cycling.²³ Food is typically available ad libitum and is often high-fat, calorically dense seed, or foods high in simple carbohydrates such as corn and fruit. These foods may actually stimulate reproduction. Most pet birds are not intended for breeding and do not have mates. In some environments, pet birds may select an abnormal mate such as their human cohabitants or cage furniture. There may be a genetic predisposition and lack of normal reproductive hormonal balance^{30,34,37} (see Chapter 3, Concepts in Behavior: Section III, Pubescent and Adult Psittacine Behavior).

Reproductively driven birds may display instinctual territorial and mate-related behaviors. These behaviors may include, but are not limited to aggression, biting, masturbation and excessive vocalization. These "undesirable" behaviors may jeopardize their value as pets, diminishing the pet-human relationship and even result in these birds losing their homes.^{30,34,37}

Reproduction is often not desired in pet birds. Egg production and hormonal cycling may lead to disease processes of the reproductive system or systemic, endocrine and metabolic disorders. Therefore, avian practitioners have sought medical and surgical methods to limit reproductive drive and hormone production.^{8,56,59}

CHRONIC EGG LAYING

Chronic egg laying in pet birds occurs when a hen lays repeated clutches or larger than normal clutch size without regard to the presence of a mate or accurate breeding season. This process often physically exhausts the reproductive tract and is a serious metabolic drain, particularly on calcium stores, all of which may predispose the hen to egg binding, yolk coelomitis and osteoporosis. Commonly affected species include cockatiels, finches and lovebirds, however, any species may be affected. Diagnosis of chronic egg laying is based on history and physical examination. There typically is a history of the hen laying large numbers of eggs with or without a pause period in between clutches. A thorough history of the home environment will often reveal several reproductive stimuli and a "mate relationship" with a member of the household or owner. Physical exam may reveal normal findings, a palpable egg in the coelom, or other secondary disease conditions such as a pathologic fracture secondary to osteoporosis. Serum chemistries may reveal hypercalcemia, hypercholesterolemia and hyperglobulinemia supportive of an ovulating hen. There may be a hypocalcemia present if the hen's calcium stores are depleted, and particularly if she is consuming a lowcalcium diet such as seed9,31,33,65 (see Chapter 5, Calcium Metabolism).

Therapy for chronic egg laying focuses on stopping egg production while altering any predisposing stimuli and correcting any secondary diseases that may be present. Pharmacologic, behavioral, nutritional, environmental and surgical options are used alone or in combination depending on the needs of the individual patient. Pharmacologic options have included medroxyprogesterone acetatea, levonorgestrelb, human chorionic gonadotropin^c, norethindrone/mestranol^d, testosterone, leuprolide acetate^e and tamoxifen^f (Table 18.1). Medroxyprogesterone acetate, though often effective, may cause serious side effects such as polyuria/polydipsia, obesity, lethargy, hepatic lipidosis, diabetes mellitus, hepatic cirrhosis and death. 9,31,63 Levonorgestrel, another synthetic progestin, has been evaluated only in Japanese quail (Coturnix coturnix japonica) and may carry the same side effects as medroxyprogesterone acetate. 72,77 Testosterone therapy interrupts the ovulatory cycle, but has variable results and is contraindicated in patients with liver disease.73 Norethindrone/ mestranol has caused severe hypertension in one Rouen duck (D. Zantop, personal communication, 2000). Human chorionic gonadotropin has demonstrated to be a safer alternative with significantly fewer side effects; however, it has not been consistently effective in managing these disorders and patients may become refractory to treatment.34,44 Tamoxifen is a non-steroidal antiinflammatory agent used as an estrogen blocker to treat women with breast cancer. Tamoxifen was administered to budgerigars presumed to be hens, but not actively laying for 38 to 46 weeks. 46 Leukopenia was a significant side effect that resolved after therapy was discontinued. An incidental finding in this study was the change in coloration of the hen's cere from brown to pink or blue. This change implies that tamoxifen does have some estrogen-blocking affects in birds. Leuprolide acetate is a long-acting gonadotropin-releasing hormone (GnRH) analog. A single injection in women and studied laboratory rodents results in an initial stimulation followed by a prolonged suppression of pituitary gonadotropins. In rats, this reduction in serum gonadotropin levels is achieved by reducing the number of pituitary GnRH receptors. Repeated monthly injections result in receptor down regulation of GnRH pituitary receptors, which causes a decreased secretion of gonadal steroid hormones. Therefore, tissues and functions that depend on these hormones for maintenance become quiescent, and diseases resulting from reproductive hormone production improve or resolve. 16,33,50,51,78

Environmental stimuli should be altered, including decreasing the photoperiod to 8-10 hours of daylight per day. Nest sites, toys and other items toward which the bird has a sexual affinity should be removed from

Table 18.1 | Summary of Medical Therapy for Reproductive Disorders

Therapy	Dosages	Comments
Leuprolide Acetate ^e	700-800*¹ μg/kg IM for birds <300 g	Administered every 14 days; 3 doses are usually adequate
	500 μg/kg IM for birds >300 g	Stable in standard freezer 9 months
Human chorionic gonadotropin*².c	250-500 IU/kg IM on days 1, 3 and 7, 500-1000 IU/kg IM	Stable in refrigerator 60 days. If a second egg is laid, repeat dose on day 3; if a third egg is laid, repeat dose on day 7
Levonorgestrel ^h	_	Not recommended
Medroxyprogesterone ^o	_	Not recommended
Tamoxifen ^f	2 mg/kg PO QD	Leukopenia
Arginine vasotocin	0.01-1.0 mg/kg IM	Stable in standard freezer
PGE (Prepidil Gel) ^a	0.025 ml/100 g 0.2 mg/kg applied topically	May freeze into aliquots and thaw prior to administration; relaxes uterovaginal sphincter while inducing uterine contractions
PGF2alpha (Lutalyse)	0.02-1.0 mg/kg IM	Does not relax utero- vaginal sphincter when inducing uterine contractions
	Topically	Applied to prolapsed uterine tissue to stop hemorrhage and shrink tissues

^{*1} Ed. Note: 1000 mg/kg has been used in recalcitrant cases.

the enclosure. Access to nesting environment or materials such as a box, other dark cavities, or shredded papers should be prohibited. In the event that a pet bird is showing nesting behavior and laying eggs in a designated site, removal of eggs from the "nest" should be avoided for the normal incubation period for each species to discourage the hen from laying further eggs to replace those removed. Any perceived or actual mate should be removed from the cage or room. In some species such as the cockatiel, visual and auditory separation from an actual or perceived mate may be necessary. A "one-person bird," which has a single household person who exclusively or primarily handles and cares for it, should potentially be viewed as having a "mate relationship" with that person. This may serve as a trigger for reproductively driven behaviors. Stimulatory petting such as rubbing the pelvis, dorsum and cloacal regions and kissing the beak should be avoided. Feeding calorically dense diets should be avoided, as mentioned previously. Interactive behaviors that simulate a "flock relationship" should be encouraged such as the bird being handled by several people in the household. The cage location and furniture (toys, perches, food dishes) should be changed and rotated periodically to discourage territorial behavior and limit reproductive drive in response to a perceived "nest site." Any nutritional prob-

Fig 18.1 | Ventrodorsal radiograph of a budgerigar hen with polyostotic hyperostosis. Note the increased density of both femurs.

lems should be corrected to improve the hen's dietary plane to reduce the severity of metabolic drain.31,53,63 Dietary alteration and reduction of caloric intake does appear to anecdotally reduce or stop egg production. This nutritional effect is often achieved by converting the pet bird from a seed-based diet to a formulated one. The exact reason for this effect is unknown, but it is common practice in poultry to reduce feed intake to stop egg production and induce molting.56 Surgical salpingohysterectomy may be elected or necessary if medical therapy is not successful and if there is no intent to breed the particular hen. Laparoscopic salpingohysterectomy may be performed as a preemptive measure on juvenile birds to prevent egg production and its associated diseases. Any secondary disease conditions also should be appropriately treated. 6,59,71

POLYOSTOTIC HYPEROSTOSIS

Polyostotic hyperostosis differs from physiologic osteomyelosclerosis in that the latter condition occurs in nonlaying hens and cocks as a result of pathologic conditions. Typically, radiographs reveal significantly increased bone density of the long bones and occasionally the vertebrae (Fig 18.1). The pathogenesis of polyostotic hyperostosis is still unclear. Many affected birds exhibit concurrent reproductive-associated activity or may suffer from reproductive-associated disease conditions. In addition, increased medullary bone density does appear to resolve radiographically with resolution of reproductive drive or disease. Hepatic disease may play a role in this condition due to the liver's role in the inactivation of estrogen. However, a recent study does not support this theory, stating that budgerigars affected by polyostotic hyperostosis had no evidence of estrogen secretion or other endocrine disease. 5,29,58,74

^{*2} Ed. Note: Should be administered with dexamethasone to avoid what appears to be immune-based response to HCG. Can be given with leuprolide acetate.

Figs 18.2a,b | Left lateral and ventrodorsal radiographs of a 3-year-old egg-bound cockatiel. The hen had been consuming a seed diet and was unable to perch for several days prior to presentation. The bird was thin (68 g), dehydrated and hypocalcemic (6.2 mg/dl), and responded to supportive care and arginine vasotocin. Egg production was controlled after egg expulsion with

Fig 18.3 | Coelomic ultrasound of the same cockatiel. Note the well-calcified egg in normal presentation for oviposition (7.5-MHz probe).

leuprolide acetate (750 μ g/kg IM every 14 days for 3 injections) and alteration of environmental stimuli. Diet was modified to include a 90% formulated diet.

EGG BINDING AND DYSTOCIA

Egg binding is defined as the failure of an egg to pass through the oviduct within a normal period of time. Most companion birds lay eggs at intervals of greater than 24 hours, and individuals may vary further. This variability may make it difficult to determine if there is a problem in the early stages of this disease. Dystocia involves the mechanical impedance to oviposition. The most common anatomic areas for this to occur are the distal uterus, vagina and vaginal-cloacal junction.31,63,73

Causes of egg binding may include chronic egg laying, oviductal muscle dysfunction secondary to excessive egg laying, calcium metabolic disease, vitamin E and selenium deficiencies, malnutrition, obesity, inadequate exercise and muscle strength, malformed eggs, mechanical tears or damage to the oviduct, oviductal infections, systemic disease, genetic predisposition and environmental stressors. Dystocia also may result when a developing egg in the distal oviduct obstructs the cloaca or causes oviductal tissue to prolapse. Oviductal torsion and oviductal or abdominal masses compressing the oviduct also may obstruct passage of an egg and result in dystocia. Breeding birds out of their natural season, egg-producing virginal hens and hens with a persistent right oviduct may be predisposed to egg binding or dystocia.31,63,73

Diagnosis

Cockatiels, lovebirds, canaries and finches are most commonly reported to be affected and seem to present with more severe clinical signs, possibly due to their small size. Clinical signs associated with egg binding and dystocia vary according to severity, size of the bird affected and degree of secondary complications. Common signs include acute depression, abdominal straining, persistent tail wagging, a wide stance, failure to perch, abdominal distension, dyspnea, and/or sudden death (Fig 18.3). An egg lodged in the pelvic canal may compress the pelvic blood vessels, kidneys and ischiatic nerves, causing circulatory disorders, lameness, paresis or paralysis. Pressure necrosis of the oviductal wall may occur. Dystocia may cause metabolic disturbances by interfering with normal defecation and micturition, and cause ileus and renal disease, respectively. The severity of the patient's condition can be estimated by the degree of depression and the length of time clinical signs have been present.31,63,73

Diagnosis of egg binding or dystocia in a severely compromised patient may be made based on history and physical examination alone, and the patient may not be stable enough to survive other diagnostic procedures. Rapid diagnosis and therapy are crucial for a successful outcome. Physical examination may reveal depression, lethargy, a thin or normal body condition, and dehydration. There may be dyspnea or an increased respiratory rate due to compression of the caudal thoracic and abdominal air sacs. The hen may not be able to perch, and may demonstrate pelvic limb paresis, paralysis or cyanosis. An egg typically, but not always, is palpable in the caudal abdomen. Cranially located, soft-shelled and non-shelled eggs may not be detected on abdominal palpation. Palpable eggs may be located within the oviduct or ectopically within the coelom, and careful abdominal palpation, cloacal examination, radiographs, coelomic ultrasound, laparoscopy and/or laparotomy may be required to determine the egg's position.31,63,73

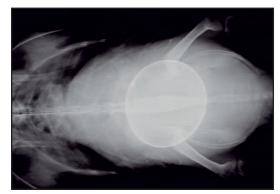

Fig 18.4a | Ventrodorsal radiograph of an eclectus hen with a history of depression and inappetence. Physical examination revealed a distended abdomen and palpable egg in the coelom. Radiographs revealed a calcified egg in the mid coelom.

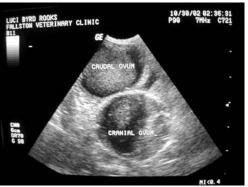

Fig 18.4b | Ultrasound of the same bird revealed a non shelled egg cranial to the shelled egg noted on the radiograph in Fig 18.4a.

Radiography and ultrasonography aid in evaluation of the position and characterization of the egg(s). There may be multiple eggs identified in the coelom due to an obstruction distally or secondary to motility disorders. Radiographs may reveal an egg in the coelom if the egg has a visible shell. The egg is typically located in the distal oviduct, in the region of the uterus (see Figs 18.2a,b, Fig 18.3). Osteomyelosclerosis of the femurs, tibiotarsi, radii, ulnas and/or spine may be visible, and a soft tissue density suggestive of an enlarged ovary in the region of the ovary may be noted, and is supportive of a reproductively active hen. A coelomic ultrasound will often reveal an egg and may identify soft-shelled or non-shelled egg(s) that may not be identifiable on radiographs (Figs 18.4a,b). Again, there may be several eggs visible within the coelom. Follicles may be visible on the ovary, indicating the potential for further ovulation and egg formation. A hematologic analysis and serum chemistries are useful to identify any predisposing and secondary diseases. A complete blood count may reveal a leukocytosis with a relative heterophilia if there is a concurrent inflammatory or infectious process. Serum chemistries may demonstrate elevated aminotransferase and creatinine phosphokinase due to skeletal muscle enzyme leakage from tissue damage, or as a result of reduced food consumption and a hypermetabolic state. Hypercholesterolemia, hyperglobulinemia are supportive of an ovulating hen. Elevated total and ionized calcium may be indicative of a cycling hen. Hypocalcemia may be observed if a hen has been consuming a calcium-poor diet or has been laying excessive numbers of eggs, resulting in depletion of calcium stores^{31,40,60,73} (see Chapter 5, Calcium Metabolism).

Treatment

Therapy varies with history, severity of clinical signs and diagnostic test results. Supportive care should include elevated environmental temperature, parenteral calcium (only if indicated), fluid therapy and nutritional support.

Broad-spectrum antibiotics are indicated if it is suspected that the integrity of the oviduct has been compromised. Analgesics are indicated if the patient appears to be in pain or if clinical knowledge of the patient's condition suggests that pain may be a part of the pathologic state. Supportive care alone is often enough to allow oviposition, although the hen should be monitored closely for deterioration of her condition, which may require further intervention. 40,63,73

Prostaglandin and hormonal therapy may be used to induce oviductal contractions. This may result in expulsion of the egg if the contractility of the oviduct is sufficient to expel the egg, the uterus is intact, the egg is within the oviduct, and there is no obstruction such as a neoplastic mass, granuloma or egg adhered to the oviduct. Studies performed in poultry have found that prostaglandin E2 (PGE2) and prostaglandin F2alpha (PGF2alpha) bind at specific receptor sites in the uterus and vagina. The uterine myometrium appears to preferentially bind PGF2alpha because it contains low-affinity and some high-affinity binding sites for PGE2 and specific high-affinity for PGF2alpha. Prostaglandin F2alpha binds at the shell receptor sites to cause a time- and dose-dependent mobilization of cellular calcium in the presence of extracellular calcium, thereby causing uterine muscle contraction. It has been demonstrated in vitro that PGE2 is itself ineffective in calcium ion mobilization, but will enhance PGF2alpha-induced calcium mobilization. This suggests that PGE2 may potentiate the ability of PGF2alpha to cause uterine contraction. In the vagina, high-affinity binding sites for PGE2 predominate. It is possible that a high PGE2 concentration in the vagina is needed to saturate high-affinity binding sites and block PGF2alpha-binding sites. This allows for relaxation of the uterovaginal sphincter and vagina. Due to the fact that fewer PGE2 high-affinity binding sites are present in the uterus, they are not likely to interfere

with PGF2alpha binding and may potentiate the action of PGF2alpha. 27,28,63,67,68

When an egg is present in the uterus, the administration of PGF2alpha and PGE2 will cause the concentration of arginine vasotocin (AVT) to increase in systemic circulation, however, PGF2alpha is the more potent stimulator of AVT release. It is suggested that prostaglandins stimulate uterine contractions, which in turn stimulate the release of AVT from the neurohypophysis, and that AVT probably acts synergistically with PGF2alpha to increase uterine contractions. Oxytocin and AVT appear to specifically affect the uterus, inducing contractions. It is important to note that PGF2alpha, oxytocin and AVT do not cause relaxation of the uterovaginal sphincter while inducing oviductal contractions. This may result in peristalsis of the egg, severe pain and/or rupture of the uterus. Prior to their use it should be determined if the utero- vaginal sphincter is open. In addition, prostaglandin and hormonal therapy does require adequate calcium to be effective. As many of these patients are severely hypocalcemic due to either malnutrition or chronic egg laying, supplemental calcium may be required prior to administration of these medications. 27,28,63,67,68

PGE2 gelg may be applied to the uterovaginal sphincter at a dose of 0.1 ml per 100-g bird. PGE2 causes relaxation of the uterovaginal sphincter while causing oviductal contractions and may be applied topically, thereby decreasing the incidence of systemic side effects. These contractions may expel the egg within 15 minutes. Contact with PGE2 gel may cause altered menses and induce spontaneous abortion in women. Therefore, it is important to flush any excess from the cloaca after egg expulsion, and to caution staff and clients regarding contact with any stool and/or urine produced. Prostaglandin F2alpha, oxytocin and AVT also will cause powerful uterine contractions. Prostaglandin F2 alpha is administered parenterally, rather than locally, and is more likely to cause systemic reactions such as hypertension, bronchoconstriction and general smoothmuscle stimulation. 27,28,63,67,68

If supportive care and medical therapy fail to induce oviposition, then manual manipulation may be necessary. Massaging the abdomen and vaginal opening may relax the vaginal sphincter and allow passage of the egg. It may be helpful to infuse lubricants into the cloaca to moisten the tissues. Careful digital pressure applied to the cranial portion of the egg and directed caudally may encourage movement through the distal oviduct and cloaca. Using a cloacal speculum, the vaginal opening of the oviduct can be dilated by inserting a blunt probe (eg, lubricated cotton-tipped swab) that is gently advanced in a twirling

Fig 18.5 | Transabdominal ovocentesis and aspiration of egg contents in a 7-year-old egg-bound cockatiel. Patient was anesthetized with isoflurane by mask induction. A 22-gauge needle and 3-ml syringe were used to aspirate approximately 1 ml of egg contents. The shell was passed approximately 4 hours postovocentesis. Complete passage of the shell was confirmed by radiography.

motion. Potential complications may include retroperistalsis of the egg out of the oviduct into an ectopic position within the coelom, rupture of the egg, oviductal trauma, oviductal laceration, oviductal avulsion, hemorrhage, and displacement of the egg or fragments into an ectopic position. If fertilization may have occurred and the egg may be fertile, it may be incubated if successfully removed intact.31,63,73

Ovocentesis may be performed to facilitate passage of an egg. Aspiration may be performed through the cloacal opening if the egg is distally located, or transabdominally if the egg is more cranially positioned. The egg is manipulated so that it is visible through the cloaca and a needle is inserted into the egg through the cloaca. The contents of the egg are aspirated into a syringe, while the shell is manually collapsed and the pieces expelled through the cloaca. (see Chapter 7, Emergency and Critical Care and Chapter 24, Diagnostic Value of Endoscopy and Biopsy). If the egg cannot be visualized through the cloaca due to a more cranial location, transabdominal ovocentesis may be performed (Fig 18.5). The egg is manually placed directly against the abdominal wall so that other abdominal organs are displaced and not damaged during aspiration. A needle is inserted through the skin and abdominal wall into the egg. The egg contents are aspirated into the syringe while the egg is manually collapsed. The eggshell remnants are expelled through the cloaca, either naturally or with clinical assistance. It is important to confirm radiographically that these eggshell pieces have been completely expelled. If these pieces are not expelled within a reasonable amount of time, approximately 36 hours, it may be necessary to irrigate the oviduct through the cloaca or laparotomy approach. A salpingohysterectomy may be performed if egg remnants are retained and the hen is not required for breeding.

Some clinicians advocate flushing the uterus postoviposition with saline, chlorhexidine or iodine to remove any shell fragments and decrease the incidence of metritis. Oviductal rupture, resulting in an ectopic egg, shell fragments and yolk coelomitis, are possible complications of ovocentesis.^{8,31,63,73} See Chapter 24, Diagnostic Value of Endoscopy and Biopsy.

Prostaglandin treatment, manual delivery and ovocentesis are contraindicated in cases of ectopic eggs, oviductal rupture, oviductal torsion and mechanical obstruction. Complications that may require surgical intervention include oviductal rupture with or without an ectopic egg, oviductal necrosis, oviductal torsion, abdominal hernia or if the condition is interfering with defecation and/or micturition. Medical therapy to reduce reproductive hormone levels and reproductive activity should be utilized to temporarily prevent further egg production. Surgical removal of an egg is required in cases of ectopic eggs and dystocia, including oviductal rupture, oviductal torsion, or mechanical obstruction, or if medical treatment is not successful. If surgical intervention is necessary, bacterial culture and sensitivity and histopathology should be performed on oviductal tissue samples. Salpingohysterectomy may be considered to prevent further reproductive complications, and any predisposing and secondary diseases should be corrected. 6,24,40,63,73

OVIDUCTAL PROLAPSE

Oviductal prolapse may occur secondary to any condition that causes chronic, excessive abdominal straining such as normal physiologic hyperplasia, egg laying or dystocia. An intracoelomic space-occupying mass also may induce prolapse of the oviduct. Predisposing factors may include abnormal or soft-shelled eggs, malnutrition, obesity, salpingitis and cloacitis. Typically, the uterus protrudes through the cloaca, often with a partial prolapse of the vagina and cloaca (Fig 18.6).^{31,63,73}

Rapid management is necessary to prevent necrosis of these tissues. Any egg that may be present should be removed, all exposed tissues cleaned, irrigated and kept well moistened to prevent desiccation. Topical antiinflammatories such as dimethyl sulfoxide may be applied, any lacerations should be repaired and all tissues should be gently replaced. Temporary stay sutures may be indicated to aid in preventing recurrence, as prolapse of the oviduct may recur and repeated replacement is often required. Bacterial culture and sensitivity of the prolapsed tissue should be performed to aid in appropriate antibiotic therapy. Complete blood count, serum chemistries, radiographs, ultrasonography and laparoscopy should be included in a complete diagnostic evaluation to identify any predisposing and secondary disease conditions. Treatment should be directed at

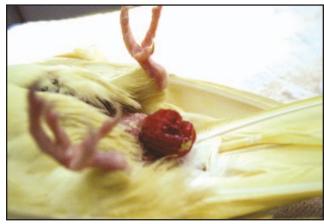

Fig 18.6 | Uterine prolapse, including partial prolapse of the vagina and cloaca, in a 7-year-old cockatiel with a history of chronic egg laying. Samples of affected tissues were taken for bacterial culture and sensitivity. Prolapsed tissues were irrigated with sterile saline, dimethyl sulfoxide was applied and tissues were reduced manually. Therapy included supportive care, enrofloxacin (15 mg/kg PO q 12 h x 14 days), carprofen (2 mg/kg PO q 12 h x 3 days). Further egg production was controlled with leuprolide acetate (750 μ g/kg IM every 14 days for three injections) and alteration of environmental stimuli.

clearing any bacterial infection and preventing further prolapse. It also is important to decrease reproductive hormone levels to prevent further egg formation, decrease the size of oviductal tissue and allow the reproductive tract to rest. Broad-spectrum antibiotics and anti-fungals should be initiated while bacterial and fungal cultures are pending. 8,31,63,69,73

Salpingohysterectomy may be considered to prevent recurrence. Predisposing factors should be corrected to prevent recurrence and secondary diseases addressed (see Chapter 35, Surgical Resolution of Soft Tissue Disorders).

UTERINE TORSION

Uterine torsion is usually diagnosed in the later stages of the disease. Birds typically present with abdominal distension secondary to coelomitis. Early clinical signs may include depression and anorexia following recent oviposition. A complete blood count often demonstrates a leukocytosis with a relative heterophilia, and serum chemistries show an elevated aspartate transferase and creatinine kinase. Diagnosis is usually made at exploratory laparotomy or laparoscopy. Many times, severe vascular compromise and necrosis of the oviduct is found, which requires salpingohysterectomy. 1.6.24,71,73

OVIDUCTAL IMPACTION

Oviductal impaction may occur following salpingitis, metritis or dystocia. Impactions may occur due to excess mucin or albumin, secondary to cystic hyperplasia of the oviduct. Inspissated egg material also may cause obstruction. Clinical signs may be vague and can include cessation of egg production, broody behavior without egg production, weight loss, anorexia, depression, constipation, diarrhea, abdominal distension, and reluctance to walk or fly. A tentative diagnosis is made through history, physical examination and supporting diagnostic tests. A leukocytosis with or without a relative heterophilia may be noted. Serum chemistries may be supportive of an ovulating hen. Radiographs and coelomic ultrasound may demonstrate a soft tissue density in the region of the oviduct, displacement of other coelomic viscera, loss of coelomic visceral detail or coelomic fluid if there is a concurrent coelomitis. Definitive diagnosis of oviductal impaction is often made at laparoscopy or laparotomy, revealing an abnormal-appearing, enlarged oviduct with or without coelomitis and adhesions. In many cases, it is necessary to clean and repair or surgically remove the oviduct. Surgery may be complicated if coelomic fluid and/or adhesions are present. 6,24,31,40,63,69,73

Bacterial culture and sensitivity should be performed on specimens from the affected oviduct, and histopathologic examination should be performed on biopsy samples. Treatment includes parenteral fluids, nutritional support, warmth and broad-spectrum antibiotics, pending culture and sensitivity results. Medical or surgical therapy to reduce reproductive hormone production and reproductive activity should be initiated, and environmental stimuli altered as discussed with chronic egg laying, to prevent recurrence.

SALPINGITIS AND METRITIS

Salpingitis is defined as inflammation of the oviduct either by an infectious or non-infectious etiology, the latter being far less commonly reported. It is generally seen associated with airsacculitis, liver disease, pneumonia, systemic infections, and ascending infections of the oviduct from the uterus or cloaca. Excessive abdominal fat has been associated with salpingitis in domestic fowl. Some of the most commonly identified pathogens are Escherichia coli, Salmonella, Mycoplasma, Pasteurella and Streptococcus spp. Newcastle disease also has been associated with salpingitis in several species. In groundnesting species such as Anseriformes and emus, nonlactose-fermenting, gram-negative bacteria such as Pseudomonas aeruginosa, Proteus mirabilis and Proteus vulgaris are commonly identified. Noninfectious causes of salpingitis include trauma and inflammation secondary to oviposition disorders, malnutrition and foreign bodies. Salpingitis is most common in adult hens but may occasionally occur in young birds as well.8,63,73,75

Metritis is a localized infection or inflammatory process

within the uterine portion of the oviduct. Metritis may occur secondary to dystocia, egg binding, oviductal impaction, systemic bacterial infection and ascending infection. Salpingitis and metritis may cause abnormal shell formation and impaired uterine contractions, and may cause infections in chicks and embryos including embryonic death. Fatalities are often associated with ovulation, egg binding or dystocia, oviductal rupture, coelomitis and septicemia.^{8,63,73,75}

Clinical signs of salpingitis and metritis may be vague and difficult to detect initially. In pet birds, these include decreased egg production, infertility, abnormally shaped eggs and mild depression. More advanced cases may exhibit anorexia, lethargy, abdominal distension, oviductal rupture, coelomitis and septicemia. There may be a leukocytosis with a relative heterophilia. Serum chemistries may or may not be supportive of an ovulating hen. Radiographs and ultrasonography may reveal an enlarged oviduct. Laparoscopy may or may not identify inflammation of the serosal surface of the oviduct. The oviduct may be thin-walled, decreased in length or have vascular congestion. The lumen may contain fluid or fibrinous exudates. Definitive diagnosis of salpingitis and metritis is based on cytology, bacterial and fungal culture and sensitivity, and biopsy with histopathologic analysis of a specimen from the oviduct.8,24,40,63,73

Therapy of salpingitis and metritis is focused on correcting any underlying or contributing causes. Antibiotic therapy for identified or suspected bacterial organisms should be initiated pending results of bacterial culture and sensitivity. Pharmacologic treatment and husbandryrelated intervention, as discussed with chronic egg laying, should be initiated to prevent further hormonal stimulation with subsequent egg production, which may perpetuate or contribute to this disease. There should be close follow-up including bacterial culture and sensitivity and fertility monitoring after treatment, as many cases are difficult to resolve completely. It is important to note that bacteria isolates from the cloaca are not equivalent to oviductal infectants, and cloacal bacterial cultures should be interpreted carefully. Severe refractory cases may require laparotomy to remove necrotic tissue and flushing of the oviduct with fluids and antibiotics. Patients suffering from severe salpingitis may require salpingohysterectomy, or this may be elected in milder cases to resolve disease and prevent recurrence if the hen is not intended for breeding. 6,63,71,73

CYSTIC HYPERPLASIA OF THE OVIDUCT

Cystic hyperplasia of the oviduct may occur from improper formation of the left oviduct or secondary to an endocrine abnormality. Additionally, the vestigial right

Fig 18.7 | Coelomic ultrasound. An ectopic egg and uterine laceration were noted on laparotomy, and a salpingohysterectomy performed. Note the calcified egg in the caudal coelom and the ovum located more cranially (7.5-MHz probe). This ovum could not be detected on the radiographs. The hen recovered fully.

Fig 18.8 | Coelomic ultrasound of an 8-year-old African grey parrot. The patient had a history of depression and inappetence. Physical examination revealed abdominal distension. Note the coelomic fluid and large ovarian cyst (7.5-MHz probe).

oviduct may become cystic and the associated ovary often has cystic changes as well. Cystic hyperplasia often contributes to salpingitis and egg binding. Clinical signs may include depression, anorexia, abdominal distension, ascites and dyspnea. A tentative diagnosis is made through history, physical examination and supporting laboratory tests, similarly to that of salpingitis and metritis. Radiographs may demonstrate an enlarged soft tissue density in the region of the oviduct. Ultrasonography may reveal an enlarged oviduct that may be fluid-filled or have obvious cysts present, with or without concurrent ovarian follicles or cysts. Laparoscopy may show a dilated oviduct filled with a white or brown mucoid fluid. Definitive diagnosis requires laparotomy with biopsy, cytology, histopathology, and bacterial culture and sensitivity.^{8,24,31,40,63,73}

Therapy to stop ovulation should be initiated due to increased risk of oviductal rupture during ovulation, oviposition and possible hormonal contribution to the cystic state of the oviduct. If bacterial infection is suspected or documented by cytology and bacterial culture and sensitivity, appropriate antibiotic treatment is indicated. Salpingohysterectomy may be required to resolve the current problem or prevent future recurrences and should be considered if the hen is not intended for breeding, as complete resolution with medical therapy alone may be difficult. ^{6,8,31,63,73}

OVIDUCTAL RUPTURE

Oviductal rupture may occur secondary to dystocia or oviductal disease. Prostaglandins, oxytocin, arginine vasotocin and ovocentesis may cause traumatic rupture of the oviduct. Clinical signs may include depression, anorexia, and abdominal distension secondary to coelomitis or the deposition of egg or oviductal contents. Radiographs and ultrasonography may reveal osteomyelosclerosis, polyostotic hyperostosis, a soft tissue density in the region of the ovary, ovarian follicles, an enlarged or cystic oviduct, a shelled or non-shelled egg, and coelomic fluid if a concurrent coelomitis is present (Figs 18.7, 18.8). Diagnosis is confirmed at laparoscopy or laparotomy. The laceration may be repaired, depending on the integrity of the tissue, or salpingohysterectomy may be performed as a therapeutic and preventive technique. 6.24,31,40,63,73

ECTOPIC OVULATION

Ectopic ovulation may result from failure of the infundibulum to retrieve an ovulated ovum, reverse peristalsis of the oviduct or oviductal rupture. Ectopic ovulation does not necessarily result in coelomitis. Internal laying is actually a common occurrence in many avian species, and the ova are usually resorbed without any problems whatsoever. Reverse peristalsis may be triggered by obstruction of the oviduct, cystic hyperplasia, neoplasia, malnutrition, trauma and stress. The ectopic ova may be resorbed without incident or may induce a severe coelomitis. 30,31,56,63,73

Clinical signs of ectopic ovulation may include transient or persistent depression, inappetence and abdominal distension, especially if there is an associated coelomitis. There may be a leukocytosis with a mature heterophilia. Serum chemistries may demonstrate an ovulating hen. Radiographs may reveal polyostotic hyperostosis and one or multiple eggs in the abdomen. It is important to

Fig 18.9 | A cockatiel hen with a history of egg laying 3 months previous is showing depression and dyspnea. Note the severely distended abdomen. Diagnosis was cystic ovarian disease.

Fig 18.10 | Laparoscopic examination of the African grey hen in Fig 18.8. Note the two ovarian cysts and several smaller follicles.

note that an ectopic ova detected by ultrasound in the absence of clinical signs may resolve on its own with no treatment, and any medical or surgical intervention may be contraindicated. It may be difficult or impossible to determine if an egg is located within the oviduct or is ectopic without laparoscopy or laparotomy, depending on its location within the coelom. If the egg is not laid within a reasonable time period and/or the patient's condition is declining, a laparotomy is indicated as an exploratory procedure. Ectopic eggs are removed by laparotomy, and any oviductal tear should be surgically repaired or a salpingohysterectomy performed. Cytology, culture and sensitivity, and histopathology should be performed in cases of oviductal rupture, cystic hyperplasia and neoplasia.8,31,40,63,73

CYSTIC OVARIAN DISEASE

Ovarian cysts have been known to occur in several pet bird species including cockatiels, canaries, budgerigars, macaws, pheasants and domestic ducks. Cyst development may be caused by endocrine disorders, anatomic abnormalities on the ovary itself and pathologic conditions of the ovary. A thorough history may reveal current or previous egg production, with an abrupt halt. Owners may even report chronic reproductive behavior without egg production or impaired reproductive performance in breeding hens.8,14,73

Advanced cystic ovarian disease may cause depression, inappetence and weight loss. Abdominal distension, often due to secondary coelomitis, and related clinical signs may be noted as well (Fig 18.9). A leukocytosis with a relative heterophilia, as well as a peripheral hypercalcemia, hyperglobulinemia and hypercholesterolemia are common findings. Radiographs may demonstrate polyostotic hyperostosis, a soft tissue density in the area of the ovary and/or oviduct, coelomic fluid and displacement of

coelomic viscera. Ultrasound may reveal a fluid-filled cyst(s) in the area of the ovary or simply coelomic fluid of an undetermined source. An ovarian cyst may be quite large and may actually fold onto itself as it grows. There may be normal ovarian follicles present as well (Fig 18.10). Abdominocentesis with cytology and bacterial culture and sensitivity should be performed in those patients suffering from associated coelomitis. It is beneficial and often necessary to perform a laparoscopic exam or celiotomy with ovarian biopsy, especially for those patients with cysts that do not resolve with medical therapy, as it is not uncommon for hens to develop ovarian cysts secondary to neoplasia and oophoritis. Laparoscopy will reveal an ovarian cyst(s), and the contents may be aspirated during this procedure. Cytology of fluid aspirated from these cysts is clear to straw-colored and of low cellularity. However, it is important to practice extreme caution during a laparoscopic exam and aspiration, as fluid from the cyst or coelom may gain access to the respiratory system through the entry hole in the abdominal air sac. Ovarian biopsy with cytologic analysis, histopathologic exam, and bacterial culture and sensitivity should be performed to identify any primary or secondary disease processes. 14,40,63,73

Treatment goals include resolution of the cyst(s) and associated disease conditions such as coelomitis, oophoritis, ovarian granuloma and neoplasia. Abdominocentesis often improves related dyspnea if there is coelomic fluid compressing the air sacs. Pharmacologic, behavioral, environmental and dietary intervention to reduce ovarian activity are indicated as production of reproductive hormones may perpetuate ovarian cysts.14 Aspiration of cysts, salpingohysterectomy and partial ovariectomy may be beneficial for complete resolution. 6,8,60,63,73 Cryosurgical destruction may be beneficial. Long-term resolution may be difficult and patients suffering from cystic ovarian disease should be regularly monitored for recurrence.8,14,63,73,78

Fig 18.11 | Ventrodorsal radiograph of a cockatiel hen with reproductive-associated coelomitis. Note the severely enlarged fluid/soft tissue density, cranial displacement of the grit-filled ventriculus, obliteration/compression of caudal thoracic and abdominal air sacs, and increased density of both femurs.

Fig 18.12 | Coelomic ultrasound of the cockatiel hen from Fig 18.11. Note the coelomic fluid and soft tissue density. Laparotomy revealed an oviductal granuloma, and the hen recovered fully in response to salpingohysterectomy and antibiotic therapy.

REPRODUCTIVE-ASSOCIATED COELOMITIS

Reproductive-associated coelomitis may encompass egg yolk coelomitis, (previous egg related peritonitis) ectopic ovulation-associated coelomitis and septic coelomitis. Coelomitis may be found in association with other diseases such as malnutrition, metabolic disorders and systemic infections. Cystic ovarian disease, salpingitis, metritis, cystic hyperplasia, oviductal rupture, oviductal and ovarian granulomas, septicemia, intestinal rupture and neoplasia may cause associated coelomitis as well.^{8,31,73}

Tentative diagnosis of reproductive-associated coelomitis is made through history, physical examination and supporting laboratory tests. The hen may have a history of egg production, which may have abruptly stopped. Clinical signs may include transient or persistent depression, lethargy and inappetence. Patients with more advanced disease may suffer from weight loss, abdominal distension, and dyspnea associated with coelomic fluid and air sac compression (Fig 18.11). It is important to note that not all patients with coelomitis will have identifiable fluid present. Supportive diagnostic tests include a complete blood count, serum chemistries, radiographs, coelomic ultrasound and analysis of any fluid recovered from abdominocentesis including cytology, culture and sensitivity. A leukocytosis with a relative heterophilia, as well as a peripheral hypercalcemia, hyperglobulinemia and hypercholesterolemia compatible with pre- and immediate postovulation may be noted. Many birds will actually be hypocalcemic due to calcium depletion subsequent to malnutrition or chronic egg laying. Some birds may have egg yolk visible in their peripheral blood smears as well as above the buffy coat in separated blood samples and lipemia is common. Radiographs may

demonstrate polyostotic hyperostosis, soft tissue density in the region of the ovary and/or oviduct, coelomic fluid, abdominal and caudal thoracic air sac compression, or even an obvious shelled or non-shelled egg, or egg remnants leading to oviductal granuloma (Fig 18.12). Contrast radiography may be helpful to illustrate organ displacement and locate any suspected space-occupying mass. Ultrasound may reveal coelomic fluid, ovarian follicle(s), ovarian cyst(s), an ovarian mass, and oviductal masses such as granuloma or neoplasia (Figs 18.13a,b). Cytology of coelomic fluid may demonstrate a septic or non-septic exudate, a transudate, or yolk or fat globules if such material is present. Bacterial culture and sensitivity should be performed on samples of coelomic fluid. Laparoscopy and/or laparotomy may be necessary to identify the causative etiology of coelomitis.8,31,40,63,73

Treatment of reproductive-associated coelomitis varies with type and severity of clinical signs. Many birds respond well to supportive care alone. Abdominocentesis is not only supportive of diagnosis but therapeutic as well, to relieve dyspnea due to air sac compression. Broad-spectrum antibiotics should be initiated in cases of suspected or confirmed infectious coelomitis while waiting for sensitivity results on fluid obtained from abdominocentesis. Corticosteroids may be indicated in cases where an infectious etiology has been excluded, but should be used judiciously due to potential serious side effects. Pharmacologic therapy may be used to stop further ovulation, reproductive hormone production and to reduce the size of the reproductive tract, which may perpetuate this condition.

Once the coelomic fluid has decreased and the patient is stable, it is beneficial to perform a laparoscopic

Figs 18.13a,b | Left lateral and ventrodorsal views of a 6year-old male budgerigar with a Sertoli cell tumor. Note the soft tissue mass in the midcoelom and polyostotic hyperostosis of the long bones.

examination. This allows direct visualization of the ovary, oviduct and other organs to help confirm etiology such as a cyst, granuloma and/or tumor. Cytology and biopsy with histopathologic examination, and bacterial culture and sensitivity should be performed on abnormal tissue. A celiotomy with or without a salpingohysterectomy may be necessary to biopsy or remove a mass, cystic oviduct or remove inflammatory debris from the abdomen, particularly if medical therapy alone is not effective. It is important to note that during laparoscopy or laparotomy there is a risk of fluid gaining access to the respiratory system via the incision through the abdominal air sacs, and often there are significant adhesions between the oviduct and neighboring viscera due to chronic inflammation.8,31,63,73

OOPHORITIS

Inflammation of the ovary results from neoplastic, mechanical or infectious causes. Infectious oophoritis often occurs as a result of spread from adjacent organs or septicemia, and is frequently bacterial in origin. Clinical signs may be vague and include anorexia, weight loss, depression, cessation of egg production, egg binding and sudden death. A diagnosis of oophoritis is made through history, physical examination, radiography, ultrasonography, abdominocentesis with coelomic fluid analysis, laparoscopy, laparotomy, and biopsy of the ovary with bacterial culture and sensitivity and histopathologic analysis. Hematology may demonstrate a leukocytosis with a relative heterophilia. Radiographs and ultrasound may demonstrate an egg or an enlarged soft tissue density in the region of the ovary, ovarian follicle(s) and ovarian cyst(s), and there may be coelomic fluid present if there is a concurrent coelomitis. If coelomic fluid is present, abdominocentesis is beneficial both therapeutically and diagnostically. Cytologic analysis as well as bacterial

culture and sensitivity should be performed on fluid recovered. Laparoscopy may demonstrate an enlarged, abnormal-appearing ovary, which may have associated hypervascularization. Persistent or chronic oophoritis may progress to granulomatous disease, which may be evident on ultrasound, laparoscopy and laparotomy. Definitive diagnosis is based on ovarian biopsy with histopathologic examination along with bacterial culture and sensitivity.8,31,40,63,73

Treatment of oophoritis includes broad-spectrum antibiotics, pending sensitivity results. Egg binding is handled as previously described. As discussed for chronic egg laying, pharmacologic therapy to temporarily stop ovulation should be initiated, as it does appear clinically that ovulation may perpetuate inflammation of the ovary. Laparoscopic exam, bacterial culture and sensitivity, and complete blood count should be repeated until culture results are negative and any leukocytosis has resolved. Reproductive performance and general condition should be carefully followed, as complete resolution may be difficult. Partial ovariectomy, usually performed with salpingohysterectomy, may be beneficial in refractory cases if the hen is not intended for breeding.8,31,63,73

OVARIAN AND OVIDUCTAL NEOPLASIA

Ovarian and oviductal neoplasia is most commonly seen in the budgerigar (Melopsittacus undulatus), cockatiel (Nymphicus bollandicus) and gallinaceous species. Clinical signs may include abdominal distension, coelomic fluid, lameness, dyspnea, depression, inappetence and chronic reproductive-associated behavior with or without egg production. Egg binding, oviductal impaction, ovarian cysts, abdominal hernia and coelomic fluid may be seen in conjunction with reproductive tract neoplasia. This fact demonstrates the extreme importance of a complete diagnostic work-up. Alteration of secondary sex characteristics such as a cere color change may occur as well. Diagnosis is supported by history and physical examination, demonstration of enlargement in the area of the ovary or oviduct on radiographs and ultrasound, and biopsy with histopathologic examination of abnormal tissues. Lymphomatosis, adenocarcinoma, leiomyosarcoma, leiomyomas, adenomas and granulosa cell tumors have been reported. 3,10,31,40,41,63,73 There have been anecdotal reports of treatment with chemotherapeutic drugs such as carboplatin (D. Zantop, personal communication, 2000); however, no consistent results have been documented to date. Prognosis for long-term recovery is grave, with no refereed reports of successful treatment. Salpingohysterectomy with partial or complete ovariectomy may have value in select patients.31,63,73 Cryosurgical ablation of the ovary and antiangiogenesis therapy may prove beneficial.

PARASITES

Ascarids and flukes have been reported to infect the oviduct from the cloaca by reverse peristalsis. Heavy infestation may cause soft-shelled and shell-less eggs, and may result in salpingitis. Anseriformes are most commonly affected. Ascarids and small flukes reportedly have been passed in eggs. Diagnosis is made by finding adult worms in the oviduct on celiotomy or necropsy, or by finding adult worms in eggs laid by affected hens. Fecal floatations should be performed, especially on ground-dwelling species, and prophylactic anthelmintic programs may be helpful in preventing severe infestations. If these parasites obstruct the oviduct, they require surgical removal or salpingohysterectomy.⁷³

OVERPRODUCTION OF EGGS

Safe numbers for egg production for different species are not definitively documented. Nutrition and environmental conditions affect safe production levels. Free-ranging psittacines typically produce one to two clutches per year; however, many captive psittacines produce far more eggs than this. While many birds show no obvious side effects, chronically overproducing hens may develop reproductive tract disorders, as well as poor body condition and feather quality. To improve long-term health in producing birds, egg production should be limited to two clutches per year in birds that show any signs of poor health secondary to overproduction. It also is recommended that all birds receive some rest period each year to prevent reproductive disorders from developing.⁷³

ORCHITIS

Infectious orchitis may occur from ascending infections, hematogenous spread or infected adjacent organs. Rarely, non-infectious causes are associated with inflammation of the testicles. Early clinical signs are vague and difficult to detect, and may include infertility, mild depression and decreased appetite. As the disease progresses, the patient may develop lethargy, inappetence and abdominal distension if a secondary coelomitis develops. Leukocytosis with a relative heterophilia may be noted. Testicular enlargement may be noted on radiographs and ultrasonography, which is a normal condition for a normal male. There also may be notable enlargement, inflammation and hypervascularization on laparoscopy. Definitive diagnosis is made by cytology, bacterial culture and sensitivity, and histopathologic examination of samples from affected testis. Therapy includes broad-spectrum antibiotics, pending sensitivity results. 12,31,73

TESTICULAR NEOPLASIA

Testicular neoplasia has been commonly documented in the budgerigar (Melopsittacus undulatus) and is often unilateral. Clinical signs include abdominal distension and one-sided paresis, paralysis, or cyanosis and hypothermia of the pelvic limb due to compression of the ischiatic nerve and blood vessels. The disease is often advanced once clinical signs are evident. Definitive diagnosis is made by testicular biopsy and histopathologic examination.¹³ Alterations of secondary sex characteristics such as cere color change from blue to brown may occur. Neoplasms reported include Sertoli cell tumor, seminoma, interstitial cell tumor and lymphosarcoma. Leiomyosarcoma and carcinoma have been reported to arise from the epididymis and ductus deferens.^{3,10} Radiographs may reveal a soft tissue mass in the region of the testicles, air sac compression, and secondary sex changes such as polyostotic hyperostosis (see Figs 18.13a,b). Treatment includes orchiectomy. Cryosurgical ablation may be beneficial. Chemotherapy with carboplatin and O,P'-DDD (mitotane)21 has been anecdotally reported if the tumor is deemed incompletely or nonresectable, or if the patient is not a good surgical candidate. However, no conclusive data have been reported to date regarding efficacy of chemotherapy.31,73

CLOACAL PAPILLOMAS

Cloacal papillomas have been noted in New World psittacine species with green-wing macaws over-represented. To date the cause is unknown, but a herpes virus etiology is strongly suspected^{7,22,39,57,62} (see Chapter 32, Implications of Viruses in Clinical Disorders). Clinical signs may include infertility due to mechanical obstruction, hematochezia, and straining to urinate and defecate. Examination of the cloaca reveals one or several fleshy masses at the mucosal border. Inserting a lubricated swab into the cloaca to evert the tissue facilitates cloacal examination (Fig 18.14). In addition, white vinegar applied to

Fig 18.14 | A 22-year-old yellow-naped Amazon parrot with a history of depression, weakness and inappetence. Note the papillomatous masses at the mucocutaneous junction of the cloaca.

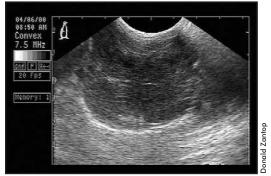

Fig 18.16 | Coelomic ultrasound of the same Amazon parrot. Note the severely enlarged liver with increased echogenicity. Liver biopsy and histopathologic examination revealed bile duct adenocarcinoma (7.5-MHz probe).

Figs 18.15a,b | Ventrodorsal and right lateral radiographs of the Amazon parrot in Fig 18.16. Note the severely enlarged liver and caudal displacement of the gritfilled ventriculus.

the cloacal wall will significantly blanch papillomatous tissue, further assisting in identification. A thorough endoscopic exam of the cloaca should be performed to rule out obstruction of the gastrointestinal, urinary and reproductive tracts. It is important to perform a full examination to detect oropharyngeal and laryngeal papillomas and hepatomegaly. It is equally as important to perform complete blood count, serum chemistries, bile acids evaluation, radiographs including contrast studies, coelomic ultrasound, and endoscopic exam of the coelom and cloaca. These tests are crucial to fully evaluate the patient, as papillomas may occur at any site of the gastrointestinal tract. Furthermore, bile duct and pancreatic adenocarcinoma are associated with papillomatous disease. 25,31,32,73,76 It is necessary to perform a liver and pancreatic biopsy for histopathologic examination to rule out early bile duct and pancreatic adenocarcinoma upon diagnosis of cloacal papilloma (Figs 18.15a,b, 18.16). Cytology, culture and sensitivity are beneficial to diagnose a secondary cloacitis. Histopathology of excised or biopsied tissue will confirm the diagnosis.31,73

Therapy includes cauterization of papillomas with silver nitrate, cryosurgery, cloacotomy and laser surgical

removal. 18,61 Autogenous vaccines and cloacal mucosal stripping have not met with consistent success.^{2,64} Imiquimodh, an immune response modifier used in humans for the treatment of anogenital warts, has been shown to decrease lesion mass and tenesmus, but it did not cause remission of papillomatous tissue.43 It is important when cauterizing papillomatous tissue with silver nitrate to flush the area profusely with saline when sufficient tissue is cauterized, otherwise normal cloacal tissue will be cauterized. Topical medications such as dimethyl sulfoxide and silver sulfadiazine cream should be applied to affected tissue after cauterization. Analgesics should be administered postoperatively as well as antibiotics if there is an associated cloacitis. Temporary spontaneous remission has been reported. Recurrence is extremely common and frequent re-examinations are necessary.31,73 Spontaneous regression has been reported.

Carboplatin chemotherapy has been reported to benefit patients suffering from bile duct and pancreatic adenocarcinoma, and does appear to be well tolerated.^{20,79}

Affected birds should be separated from the non-affected to prevent possible transmission.^{8,31,73} It is beneficial to

Fig 18.17 | Prolapsed cloaca in a 5-year-old male umbrella cockatoo. History included chronic masturbation and intermittent partial cloacal prolapse.

Fig 18.18 | The same umbrella cockatoo after manual cloacal reduction and cloacopexy.

perform a thorough cloacal examination, particularly on New World psittacines, during routine health examinations, as affected birds should be isolated to prevent potential spread to non-affected individuals. Healthy chicks have been raised from artificially incubated or fostered eggs from affected pairs.^{31,73}

CLOACAL PROLAPSE

Cloacal prolapse may occur secondary to chronic straining from masturbation, egg laying, space-occupying abdominal masses, and inappropriate weaning and social behavior. Physical examination will reveal prolapsed tissue through the vent that may be intermittent or persistent (Fig 18.17). Careful cleaning, irrigation and lubrication of prolapsed tissue are a necessity. Affected tissue should be examined for necrosis, and any adhered egg should be removed. Cytology and bacterial culture and sensitivity should be performed on prolapsed tissue to aid in antibiotic therapy. A complete blood count, serum chemistries, radiographs, ultrasound and endoscopic exam of the coelom and cloaca are useful to determine any other predisposing cause.31,73 Chronic reproductive-associated behavior and straining secondary to masturbation may respond to pharmacologic therapy such as leuprolide acetate or environmental manipulation to decrease reproductive stimuli. Cloacopexy and the use of temporary stay sutures may be helpful in temporary or permanent reduction. However, those procedures interfere with movement of the cloaca and may alter defecation and micturition^{4,66} (Fig 18.18). Ventplasty may decrease the vent opening and prevent further prolapse if the vent has become flaccid (see Chapter 35, Surgical Resolution of Soft Tissue Disorders). Clomipramine hydrochloride and phenylpropanolamine administration has been anecdotally reported to contract the vent orifice and assist in the resolution of prolapse of

the cloaca (D. Zantop, personal communication, 2003). Salpingohysterectomy with partial ovariectomy or orchiectomy may be beneficial in those patients refractory to medical therapy. Broad-spectrum antibiotics should be initiated, pending bacterial culture and sensitivity, because primary and secondary bacterial infections are common.^{8,31,63} See Chapter 3, Concepts in Behavior.

CLOACITIS

Cloacitis may result from both infectious and non-infectious processes. Cloacal prolapse, cloacal papillomas, cloacoliths and bacterial infections may cause inflammation of these tissues. This may result in secondary urogenital and/or gastrointestinal disease due to the anatomic relationship to the cloaca. Cytology with bacterial culture and sensitivity should be performed. Appropriate antibiotics or anti-inflammatory therapy may be indicated. Dimethyl sulfoxide may be used to reduce inflammation with no systemic side effects, and swabbing the cloaca with petroleum jelly will prevent fecal and urate accumulation on the cloacal surface with subsequent irritation.⁷³

CLOACOLITHIASIS

Cloacolithiasis is infrequently noted in pet birds. It may result from previous egg binding, infectious cloacitis, malnutrition or neurologic disease of the cloaca. Cloacoliths should be manually or surgically removed. Cloacal cytology with bacterial culture and sensitivity should be performed. The identification of anaerobic bacteria, notably *Clostridia* sp., is a common finding often associated with a fetid odor. Since routine aerobic cultures will not isolate these organisms, Gram's stains of the feces should be performed. Broad-spectrum antibiotics should be initiated, pending culture results.

Improved nutrition through diet change should be initiated. Patients should be monitored closely for recurrence, and prognosis for return to normal breeding performance is poor.⁷³

CLOACAL NEOPLASIA

Cloacal carcinomas are infrequently reported in pet birds. An endoscopic examination of the cloaca should be performed, and the patency of openings into the urodeum, proctodeum and coprodeum should be noted. Definitive diagnosis is made from histopathologic analysis of biopsy samples. Neoplastic masses should be surgically removed, with caution not to damage the openings to the gastrointestinal, urinary and reproductive tracts. 3,41,42,73

OTHER CLOACAL DISEASES

Other cloacal diseases include cloacal strictures and excessive vent feathering. Cloacal strictures may be gently manually dilated with the use of a speculum. Excessive feathering around the vent may cause infertility; prior to breeding season, these feathers should be removed by trimming or pulling.⁷³

REPRODUCTIVE HORMONE-RELATED FEATHER PICKING

Birds pick their feathers for several different reasons. Avian veterinarians often cannot elicit a cause from a complete history, physical examination and diagnostic work-up. In some avian patients, history may reveal reproductive-related behaviors such as breeding, masturbating, regurgitation and failure to molt. Physical exam

may demonstrate removal of one or several types of feathers, rough feather condition of any remaining feathers, and the patient may become reproductively stimulated during the examination. Serum chemistries panels may reveal elevated serum calcium in hens (provided they are not calcium deficient) and hypercholesterolemia. Radiography may demonstrate an enlarged gonad(s) and/or polyostotic hyperostosis. Ultrasonography and laparoscopy may reveal ovarian follicles, ovarian cysts, an enlarged oviduct or enlarged testicles. The diagnostic work-up must be extensive to rule out any other possible diseases. Serum estradiol, progesterone and testosterone level tests are available, although normal values are not known for every avian species. Pharmacologic treatment, behavior counseling and environmental changes to reduce reproductive drive and hormone levels as discussed with chronic egg laying are recommended. Response to treatment is important therapeutically and diagnostically. Treatment failures may be due to the presence of non-reproductive-related disease and concurrent disease. It is important to note that a full history and diagnostic work-up must be performed prior to establishing a diagnosis of reproductive-related feather disease. Many of these birds molt heavily after starting therapy and this should not be interpreted as a deleterious side effect.8,11,48

Endocrine Considerations

K. STORMY HUDELSON, BS, DVM, Dipl ABVP-Avian; PAUL M. HUDELSON, BA, MA

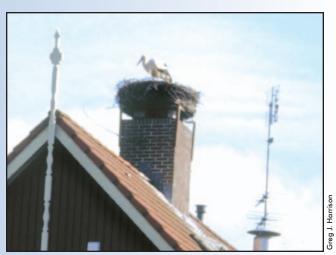

Fig 19.1 | The European stork is a perfect example of birds learning to modify stressors.

Stress

Many things can be stressful, including isolation, ²⁰ weather change, ¹⁰¹ separation from mate, forced exercise, ⁹⁵ fear, ⁶⁸ starvation, ⁶⁷ handling, ⁶⁰ toxins and abnormal physical conditions, such as infection, trauma and pain. ⁹⁵ Stress involves a cascade of physiologically adaptive responses. These responses can be demonstrated in altered behavior, such as aggression, escape attempts, vocalizations, changes in feeding and drinking, feather picking, repetitive movements and suppression of reproduction. ⁷⁹ These varied physiological reactions do not constitute a uniform set of adaptive responses occurring in a predictable temporal fashion (Fig 19.1). ⁹³ The most reliable response to stress is an elevation in circulating corticosterone levels. ^{93,60}

In a set of experiments, the temporal association of stress responses was determined. Juncos measured at handling and again in 30 minutes demonstrated a fourfold increase of corticosterone levels. 60 In chickens given a continuous infusion of adrenocorticotropic hormone (ACTH), the corticosterone response was within 2 hours. Other significant indicators of stress were elevation of glucose by 12 hours; increased liver weight along with increased hepatic lipid and decreased moisture by 18 hours; decreased relative weight of the spleen by 24 hours; elevated heterophil:lymphocyte ratio by 2 days; decreased body weight and relative weight of the bursa of Fabricius, as well as the weight of the thymus, by day 4; and decreased liver-soluble protein content by 12 days. Elevations in cholesterol, triglycerides, high-density lipoproteins, corticosterone and glucose were found to be reliable indicators of stress.111 Polydipsia and polyuria were evident in chickens within 1 to 2 days of ACTH infusion.94 Feed intake was slightly elevated over the

week of ACTH infusion; however, body weight was 20% lower 1 week postinfusion at the end of the experiment. However, apparently due to a decrease in digestion of proteins, carbohydrates, dry matter and gross energy. Fat digestion was unaffected. Digestion was more affected than absorption and returned to control levels within 1 week. Post-ACTH infusion, as digestion returned to normal, absorption of nutrients was reduced. Losses of skeletal muscle from prolonged gluconeogenesis by catabolism of muscle protein from excess corticosteroids were not recovered by the end of the experiment (1 week). However, body weight was 20% and the experiment (1 week).

Migratory birds undergoing a prolonged fasting period did not demonstrate elevated corticosterone levels until fat stores were depleted to less than 5% of body mass. At that point, muscle catabolism occurred due to a moderate elevation of corticosteroids. Further secretion of corticosterone is inhibited when additional stressors are encountered. This may be a means to continue migration by using muscle protein for energy while finding a suitable landing area at which to feed. Increased corticosterone levels coupled with decreased fat stores stimulate appetite and foraging. In non-migratory birds forced to exercise, corticosterone levels were elevated proportionally as the intensity of the exercise increased.

Corticosterone also affects various behaviors in birds. It can cause an inhibition of territoriality, rearing of young and behavior associated with breeding, without affecting luteinizing hormone or testosterone levels (see Table 19.2). ¹²⁶ Severe stressors cause regression of the reproductive system in chicken hens. ¹⁰⁶ Pharmacological doses of corticosterone can induce a preovulatory surge of luteinizing hormone and ovulation, whereas dexamethasone blocks ovulation, possibly because it suppresses corticosterone. ¹⁰⁶

Fear behaviors are seen with increased corticosterone levels; they may be attenuated with vitamin C supplementation. Exogenous corticosterone induces protein catabolism and causes chickens to seek a high-protein diet. Feather picking is associated with increased corticosterone levels. This suggests that some feather-picking behavior may be a stress response to protein catabolism.

Glucocorticoids induce epinephrine synthesis while ACTH stimulates epinephrine and norepinephrine release. These catecholamines augment, through β -adrenergic receptors, and suppress, through α -adrenergic receptors, the plasma corticosterone responses to ACTH. Increased epinephrine stimulates glycogenolysis, gluconeogenesis and lipogenesis. Norepinephrine helps maintain blood pressure.

Stress-induced immunomodulation has both beneficial and deleterious effects. Exogenous glucocorticoids or increased circulating levels of corticosterone cause involution of the thymus, bursa of Fabricius and spleen.35 With early destruction of the bursa, the bursal hormones are not produced. This leads to a future stress hyporesponsiveness.²⁴ The composition of white blood cells moves toward an overall decrease in leukocytes, except heterophils, leading to an increased heterophil:lymphocyte ratio. 45 This decrease in leukocytes is partly due to the cells remaining in lymphoid organs.24 A decrease in lymphocytes causes an overall suppression in antibody production.79 In addition, glucocorticoids decrease inducible cellular cytotoxicity, lymphoproliferation, T-cell immunity, interleukin-2 and γ-interferon production.65 Taken together, these responses may increase susceptibility to viral and other infectious agents.45

Lymphocytes themselves secrete ACTH and therefore boost circulating corticosterone levels following antigenic challenge. The increase in corticosterone appears to cause a shift to increased T-helper cells and decreased T-suppressor cells in the spleen. Macrophages are activated as they phagocytize an antigen. The activated macrophages secrete interleukin-1. Interleukin-1 increases secretion of corticotropin-releasing factor and ACTH, and activates lymphocytes, which increase production of ACTH. Prolonged stress prior to antigenic stimulation may blunt the ACTH and interleukin-1 response. The increased glucocorticoids cause the redistribution of circulating T-cells to secondary lymphoid tissues where antigens may be sequestered.

Some amount of corticosterone is important in the immune response. Corticosteroids cause enhanced lymphocyte activity and the production of antibodies. Corticosteroids and ACTH later act in a negative feedback manner to regulate and control the process of antibody production by inhibiting lymphocyte activities and reducing the responsiveness to stimuli. 82 There is a significantly lower corticosterone response postantigenic stimuli in chicken strains that have autoimmune thyroiditis or avian scleroderma (another autoimmune disease). 56 This lack of response would attenuate the negative feedback of corticosterones on ACTH and may allow for a more pronounced immune response causing the autoimmune disease.

The administration of dexamethasone has been shown to depress ACTH and corticosterone for more than 24 hours. ⁵⁶ In addition, both dexamethasone and prednisone decrease body weight gain, the number of natural killer cells, the number of lymphocytes in the spleen, production of interleukin-2 and γ -interferon by T-cells of the spleen. ⁶⁵ These steroids also cause splenic atrophy,

increased body fat deposition, decreased percentage of immunoglobulin-A and immunoglobulin-M-bearing B-cells, decreased lymphoproliferation and increased susceptibility to *Eimeria* spp. ⁶⁵

The use of dexamethasone may cause more problems by not allowing for the natural effects of corticosterone. If steroid administration could be beneficial to the patient, the use of corticosterone or ACTH may be a better choice. When chickens infected with Streptococcus faecalis were given corticosterone at 30 mg/kg in feed in combination with ampicillin, the chickens were able to increase weight better than without corticosterone. Ampicillin alone did not alter the course of disease. Corticosterone alone was as good as the combination of ampicillin and corticosterone in most cases. 48 Another study demonstrated better resistance to Escherichia coli challenge exposure when corticosterone was given at 40 mg/kg in feed.49 Pericarditis was reduced from 78% to 7%. No antibiotics were given. Resistance to respiratory infections was improved in pigeons given corticosterone, because of improved tracheal mucociliary transport.72 Realizing that simply restraining a bird can elevate endogenous corticosterone tremendously, it may not be necessary to even treat with corticosterone, but simply to catch the bird several times.60

On the other hand, corticosterone depresses resistance to viral and *Mycoplasma gallisepticum* infections in poultry. When chickens were given drugs to block the adrenal gland's production of corticosterone, fewer deaths and more effective cell-mediated immunity were seen to Newcastle disease and *Mycoplasma gallisepticum* infections. Additionally, a rapid remission of Marek's tumors was demonstrated. Torticosterone and dexamethasone may decrease inhibin levels; this in turn increases follicle-stimulating hormone, which may cause follicle abnormalities. Handling birds could conceivably exacerbate these diseases. Clinically, the use of mitotane (o,p'-DDD) has shown promise in controlling some neoplasias, viral infections and feather picking (G. Harrison, personal communication, 2002).

Many clinical problems may be due to a stressful environment (i.e., fatty liver disease, feather picking and reproductive abnormalities). Many patients present with liver disease. In theses cases, the liver may not be able to metabolize natural or exogenous glucocorticoids. Appropriate nutrition is imperative to the health of our patients; however, nutrition and other therapies cannot override conditions brought on by chronic stress. The best therapy for many of the diseases we encounter should be directed toward the psychological well-being of our patients (Figs 19.2, 19.3 and Tables 19.1, 19.2).

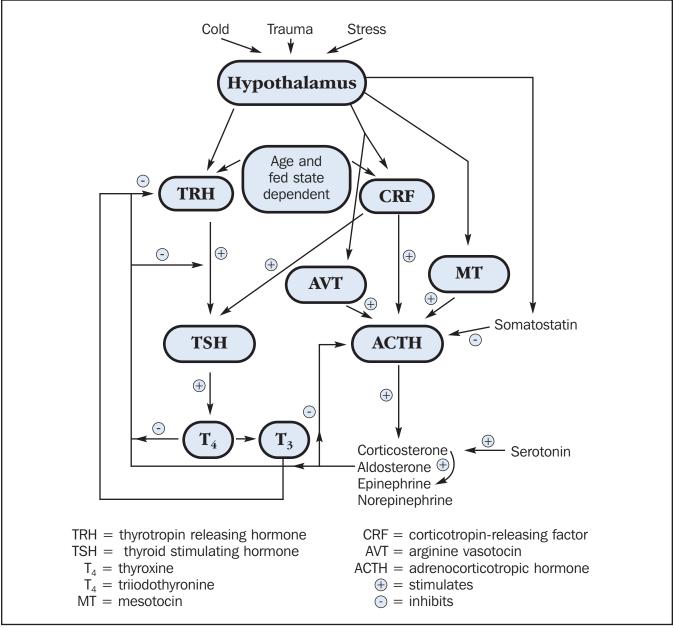

Fig 19.2 | Hypothalamo-Pituitary-Adrenal Axis Hormones

Growth

Growth primarily involves cell proliferation, but also may result from cell hypertrophy. The primary hormones involved with growth are: growth hormone (GH), tri-iodothyronine (T₃) and insulin-like growth factor-1 (IGF-1). Contradictions in the literature due to variable experimental designs are exacerbated by the different actions of various hormones, depending on age and nutritional status. Fig 19.4 demonstrates an overview of hormonal interactions. Tables 19.3-19.5 delineate what effects these hormones have on growth and body condition.

The reader should be aware that all available growth studies look at growth in poultry. There may be some undiscovered variations among other species of birds. There are many hormones active during embryogenesis. Insulin and insulin-like growth factors are reported to stimulate embryonic metabolism, growth and differentiation. Some growth factors appear to have more specific actions in embryogenesis, though many seem to have synergistic activity with IGF-1. Table 19.6 lists some of the growth factors and their respective actions.

As poultry moves into its rapidly growing phase at 3 to 4 weeks posthatch, GH and IGF-1 levels peak and then gradually decline to their minimum concentrations at about 8 weeks posthatch. During this period of rapid growth, administration of exogenous GH or IGF-1 demonstrates no effect on growth rate.^{22,85} As endogenous nutrient partitioning is shifted toward greater fat deposition, as seen with increasing age and cessation of

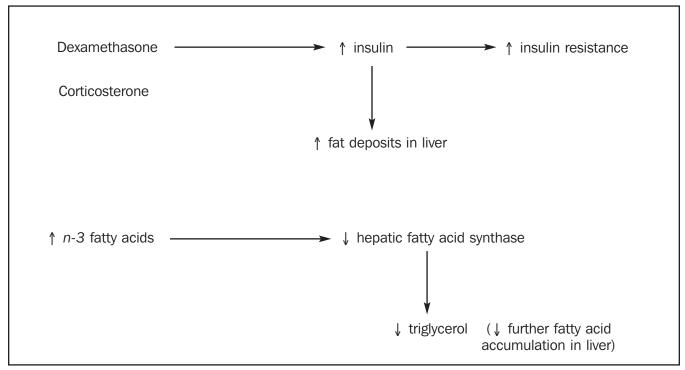

Fig 19.3 | Fatty Liver

growth, exogenous GH is effective in decreasing fat and increasing muscle formation. ⁸⁵ GH in adult birds is a potent lipolytic hormone and also increases blood glucose levels. ²² There does not appear to be a diabetogenic effect, as seen in humans administered GH, possibly due to increased sensitivity of peripheral insulin receptors. GH also can block glucagon-induced lipolysis resulting in antilipolytic activity. Exogenous GH, in 8- to 9-week posthatch poultry, reduced feed intake and body weight gain. ¹¹⁹ The reduction of feed intake may be secondary to GH's reduction of neuropeptide Y protein, a potent appetite stimulant. ¹¹⁹

In growing birds, GH decreases T_3 degradation resulting in elevated T_3 concentrations.³⁰ The effect of T_3 is developmentally regulated. Exogenous GH produces a hyperthyroid response in late embryogenesis, newly hatched and adult birds.^{29,75} This effect disappears during the rapid growth phase, most likely due to masking by high endogenous GH and T_3 levels.^{30,119} In mammals, GH must bind to two sites of the receptor, similar to antibodyantigen cross-bridging. Therefore, high levels of GH may block signal transduction.³⁷

Growth hormone receptors and growth hormone-binding proteins also may play an important part in agerelated actions. In young birds, growth hormone receptors are low, and GH and growth hormone-binding protein levels are high. Exogenous GH would have little to no effect. In adult chickens, growth hormone receptors are elevated and GH is low. In this case, exogenous GH may initially have stimulatory effects; however, at some

point, the excess GH may be bound by increased levels of growth hormone-binding protein and GH-induced down regulation of growth hormone receptors.⁵³ Binding of GH may keep it from attaching to receptors, but also may prolong its half-life.⁵³

 β -adrenergic receptor agonists, epinephrine and norepinephrine also appear to have a significant role in growth and body composition. When clenbuterol (β -adrenergic receptor agonist) was given orally, growing chickens decreased their fat mass, while increasing their muscle mass, weight gain and gain-to-feed-intake ratio. These changes could be from a direct effect on muscle and adipose tissue, modification of blood flow, central nervous system control of feed intake and/or action of other hormones (ie, T₃, corticosterone, insulin, GH).

The majority of information on growth in birds is still quite controversial, with many questions left unanswered. Those answers found in poultry may have little to offer other species of birds.

Thyroid

Thyroid hormones influence or are influenced by almost all physiological, environmental and nutritional parameters. When interpreting the literature, it is important to correlate the age of bird with the actual dose of drugs used in the experimental design to interpret the data correctly.

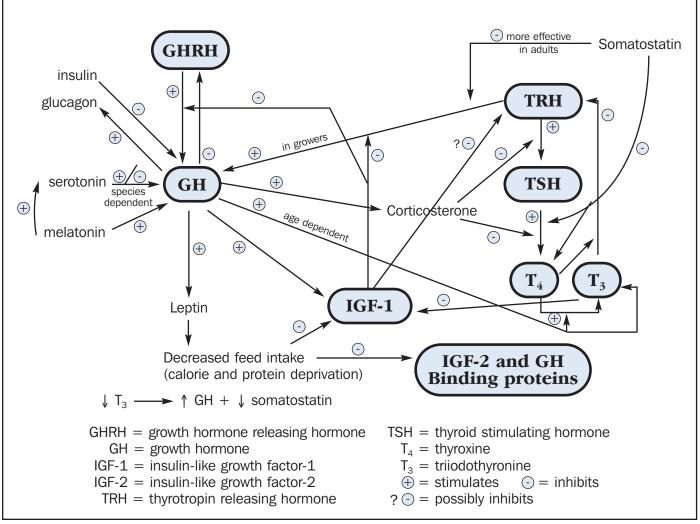

Fig 19.4 | Growth Hormone

Increases	No Effect	Decreases
 Differentiation and proliferation of target cells (i.e., muscle) Glucose Fat in growing birds Insulin-like growth factor-1 in selected muscles of adults Exogenous GH: Fat birds between 3-5 weeks of age, lipolytic Other birds lipogenic Increase insulin and tryglycerides at 24 days of age Increase tibia length between 2-24 days of age In adult birds, large increase in T₃ Large increase of T₃ at late embryo early hatch Conversion of thyroxine (T₄) to triiodothyronine (T₃) Moderate increase of T₃ at growth stage due to decreased degradation of T₃ 	Exogenous GH 2-24 days post hatch no effect on growth, feed intake, carcass protein, 8-9 weeks post- hatch no effect on IGF-1 levels	 Fat in adults Neuropeptide Y Feed intake at 8-9 weeks post-hatch Muscle growth at 8-9 weeks old Hypothalamic epinephrine Degradation of T₃

Table 19.4 | Effects of Insulin-like Growth Factor-1 (IGF-1)

Increases	No Effect	Decreases
Metabolism, growth, differentiation, organogenesis of the embryo Fat in growing poultry Glucose uptake Amino acid uptake and protein synthesis Inhibition of protein degradation Proliferation of turkey and chicken myoblasts Peripheral tissue sensitivity to insulin Exogenous IGF-1 increases heart weight and muscle breakdown in 3-week-old chickens	Exogenous IGF-1 has no effect on growth or protein synthesis rate	 Insulin Insulin:glucagon ratio GH lipolysis in growing birds Muscle growth in chickens greater than 8 weeks posthatch Muscle weight in 3-week-old chickens Glucose

Table 19.5 | Effects of Triiodothyronine (T₃) on Growth

Increases/Stimulates	Decreases	Low Levels of T ₃
Accretion of muscle protein during growth Muscle mass and feather development in growers	GH IGF-1: may be age-dependent at low dose Fat in growing birds Muscle mass due to decreased protein synthesis in non-growing birds	Increase GH Decrease skeletal, muscle and feather development in growers Decrease cardiac ventricle and pectoral mass in growers

Table 19.6 | Growth Factors Involved with Embryogenesis

Increases/Stimulates	Factors
Insulin-like Growth Factors (IGF)	• IGF-1 most important (see Table 19.4)
Epidermal Growth Factor (EGF)	• With IGF-1 and Fibroblast Growth Factor (FGF) stimulates proliferation of heart mesenchymal cells
Fibroblast Growth Factor (FGF)	See EGF Stimulates: • Muscle and bone development • Differentiation of blastoderm cells into erythropoietic cells • Proliferation of preadiposites • Proliferation of chondrocytes with transforming growth factor-β (TGF-β) • With IGF-1 proliferation of chicken myoblasts
Nerve Growth Factor (NGF)	Neural development
Transforming Growth Factor- β (TGF- β)	Includes several TGF-βs, e.g.: • Inhibin/Activin subunits • Bone Morphogenic Protein-4 (BMP-4) • Glial Cell-Derived Nerve Growth Factor (GDNF) • Muellerian Inhibitory Substance (MIS) • Platelet-Derived Growth Factor (PDGF)
TGF-β	Decreases: • DNA synthesis and melanocyte formation in neural crest cells • Collagen production Stimulates: • Expression of fibronectin • Proliferation of chondrocytes with FGF and adiposites • Limb formation • Synthesis of non-collagen protein • Muscle cell differentiation
Inhibin	Blocks release of follicle-stimulating hormone (FSH) With activin may play an antagonistic role in paracrine regulation of embryonic gonadal steroidogenesis
Activin	See Inhibin • Stimulates release of FSH • Determines right and left asymmetry
Bone Morphogenic Protein-4 (BMP-4)	Stimulates: • Osteoinduction • Gastrulation • Neural crest cell apoptosis
Glial Cell-Derived Nerve Growth Factor (GDNF)	Increase survival of motor neurons by reducing programmed apoptosis
Muellerian Inhibitory Substance (MIS)	Muellerian duct regression in males
Platelet-Derived Growth Factor (FDGF)	Stimulates transformation of chicken myoblasts Inhibits differentiation

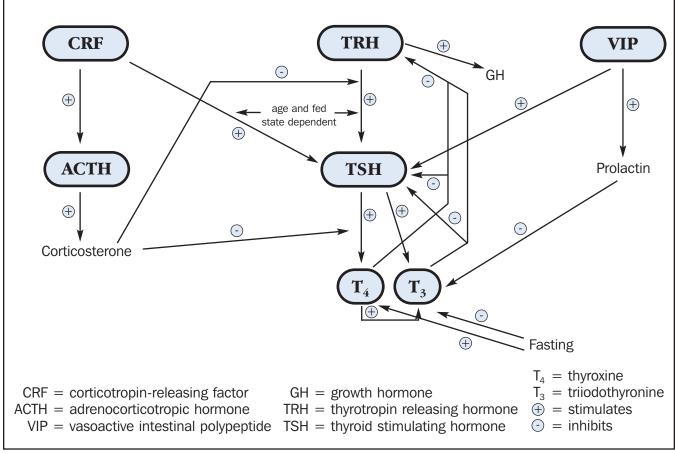

Fig 19.5 | Thyroid Hormones

In chickens of all ages, thyroid stimulating hormone (TSH) stimulates the release of predominately thyroxine (T₄) and lesser amounts of triiodothyronine (T₃). Age changes the mechanisms controlling TSH release and the peripheral productions of T₃. In the embryo, corticotropin releasing factor and thyrotropin releasing hormone may control TSH release. 105 Thyrotropin releasing hormone stimulates the release of growth hormone (GH), which inhibits degradation of T₃ through the growing phase (see Growth section, this chapter). Growing chickens respond differently to thyrotropin releasing hormone when fasted. During a 1-day fast, thyrotroph cells increase their sensitivity to thyrotropin releasing hormone and corticotropin releasing factor. However, these cells do not release TSH because fasting induces a decrease in thyrotropin releasing hormone secreted by the hypothalamus. 40 Fasting also increases corticosterone levels, which inhibit secretion of thyrotropin releasing hormone and, thus, TSH release. This was demonstrated in chickens with one injection of 40 µg of corticosterone.40

As chickens mature, they are less responsive to thyrotropin-releasing hormone effects on TSH. TSH appears to be more sensitive to circulating concentrations of T_3

than T_4 . ¹⁰⁵ Figs 19.2, 19.4 and 19.5 elucidate some of the pathways involved in thyroid regulation.

PHOTOSTIMULATION

Increasing day lengths induce photostimulated reproductive activity and postnuptial molt. It has been suggested that this onset of photostimulation combined with endogenous thyroid hormones organize the events of seasonality. 124 When American tree sparrows (Spizella arborea) were moved from short to long days, T₄ along with circulating luteinizing hormone increased early during photostimulation, peaking between weeks 1 and 2. This was followed by luteinizing hormone-releasing hormone and luteinizing hormone peaking between weeks 2 and 4. By week 6, gonad development was near maximum. Thyroid activity peaked during copulation. 25,97,123,124 The postnuptial molt began at week 9 and ended by week 18.97 A series of experiments on intact and variably timed thyroidectomies concluded that thyroid-dependent gonadal growth was programmed during the first 7 days of photostimulation. Photorefractoriness and initiation of molt were programmed between 7 and 21 days of photostimulation.53 T3 failed to program birds for these events. This suggests that T₄ directly or non-T₃ metabolites are the responsible hormones. 124

Cases

Most reports of thyroid conditions in birds involved those genetically designed for hypothyroidism (ie, chickens of the obese strain, and white carneaux pigeons). The only case of confirmed hypothyroidism in a psittacine was reported in a scarlet macaw. This report described contour feather loss, no indication of feather regrowth and excess subcutaneous fat. Skin biopsies demonstrated a catabolic state, a finding inconsistent with hypothyroid cases. A TSH stimulation test confirmed that the bird was hypothyroid. The bird responded to thyroid hormone replacement in the water at 0.015 mg/kg BID, which was later reduced to daily therapy.89 It was not clear if this was a lifelong therapy or was discontinued after the resolution of signs. If the bird was taken off thyroid medication and remained euthyroid, it could have been due to a resolving thyroiditis, stressful environment and/or inadequate nutrition.

Goiter has often been associated with iodine-deficient budgerigars. Another incidence of goiters was reported in a goose flock of 2300 birds.66 Though geese feeding on rapeseed meal develop goiters, rapeseed was not part of this flock's ration. The major pathological findings were increased relative thyroid weight, fat accumulation, and retarded growth and plumage development. One group of birds was treated with iodine and another group was not. After 55 days, both groups improved. A hunt for possible goitrogenic substance was not successful.66 The two study groups were put in less dense environments. This may have resulted in less stress, therefore less circulating corticosterone and less suppression of thyroid activity. A recent report found a disproportional number of macaws with hyperplastic goiter. Seventy-five percent of these cases were in blue and gold macaws (Ara arauna). The cause was not determined. 104

Avian muscular dystrophy in chickens has been treated by thyroidectomy. Maintenance of low T₃ plasma levels with exogenous T₃ replacement alleviated signs attributable to the disease. These chicks demonstrated a large increase in T₃ maximum binding capacity in dystrophic muscles.⁷³

Cysts, adenomas and adenocarcinomas have been reported infrequently in several genera of birds. As intensive breeding and pollution with hormonally disruptive chemicals increase, thyroid disease may be reported more frequently.

TESTING

Most available thyroid tests are designed for humans or dogs. These tests are not usually able to detect the relatively low concentrations of T₄ in the avian patient.⁴³ When testing for thyroid hormones, it is important that

the test be validated for birds. The necessity of incubating serum samples with proteolytic enzymes, and then precipitating with ethanol to avoid binding proteins in the serum has been demonstrated. Without these extra steps, the test will be inaccurate. Another source of difficulty is the lack of good reference ranges. With so many variables capable of altering thyroid levels, it is important that those birds used for reference ranges be fed, housed and cared for optimally.

 $\rm T_4$ blood levels fluctuate normally during a 24-hour cycle, generally being higher in the night and during a fast. ⁸⁴ To measure $\rm T_4$ activity more accurately, a TSH stimulation test is required. Recently, a stimulation test in several genera of birds has been developed using synthetic human thyroid stimulating hormone. ⁴⁴ It was found that a 0-hour baseline blood sample, TSH at 1.0 IU/kg IM and a second blood sample in 6 hours gave consistent results.

Pancreas

ENDOCRINE-GLUCOSE REGULATION

Glucose regulation is the primary endocrine function of the pancreas. Effective glucose metabolism also maintains normal protein and lipid metabolism. Neural, retinal and adrenal tissues require glucose. The avian liver is the primary source of glucose to the plasma by its interaction with the pancreas. The pancreas releases the proper ratio of insulin and glucagon. The combination of hormones and absorbed nutrients work together in the liver to release products of digestion in dynamic response to the bird's needs. After a bird feeds, plasma glucose and amino acid levels increase causing insulin release from the pancreatic B-cells. Insulin aids hepatic enzymes in glycogenesis. In the liver, protein synthesis and lipogenesis produce approximately 95% of lipids through insulin stimulation. Thyroid hormones augment the process. Insulin is therefore an anabolic hormone.

In the fasting state, the liver is important for retrieving energy sources and making them available. With lower blood glucose concentrations, insulin levels are low and glucagon levels are high. At the liver, glucagon causes lipolysis, glycogenolysis and stimulates gluconeogenesis. Glucagon is therefore a catabolic hormone. The glucagon insulin responses to food intake maintain stable blood glucose levels. A variety of species of birds demonstrate only small declines during prolonged (5 to 7 days) fasts. 4 We have seen emaciated birds with only slightly decreased blood glucose. A study in migrating garden warblers (*Sylvia borin*) found that glucose utilization rate is reduced as food deprivation continues to

about 7 days. These experiments suggest that during migration, a period of prolonged fasting, glucose utilization may be supplanted by oxidation of fatty acids. 113

Adipose, kidney and muscle tissues each play a role in maintaining energy sources. The kidney can provide up to 30% of glucose by gluconeogenesis. Adipose tissue is important in providing lipids through lipolysis.³⁹ During a catabolic state, muscle tissue itself may be broken down (see Stress section, this chapter).

Cholecystokinin, glucagon and a mixture of absorbed amino acids strongly stimulate, whereas glucose only weakly stimulates insulin release. Insulin enhances protein synthesis and is required for embryonic myogenesis and muscle structural proteins in adult birds. At the level of the muscles and adipocytes, insulin increases glucose transport carriers. These proteins increase the transport of free glucose from the extracellular fluid across the cell membrane. Insulin aids transport of amino acids into cells. Insulin, or its hypoglycemic effect, causes glucagon release and results in an increase in free fatty acids. Therefore, insulin's overall effects are to remove glucose and amino acids from circulation, increase lipidemia and inhibit gluconeogenesis.

Free fatty acids and cholecystokinin stimulate glucagon release from the pancreatic A-cells. In contrast to other avian species, ducks also release glucagon in response to insulin and somatostatin. Glucose inhibits glucagon release. Glucagon suppresses leptin, a hormone that suppresses appetite, T₃ and T₄. 3,83

Somatostatin controls the ratio of insulin to glucagon released from the pancreas. Islet cells appear to be contiguous with each other and share intra-islet extracellular fluid. Somatostatin from pancreatic D-cells inhibits secretion from all other islet cells. Glucagon is the most sensitive and pancreatic polypeptides are the least sensitive to somatostatin. At the level of the gut, somatostatin decreases intestinal absorption of glucose and lipids. This hormone's actions allow a dynamic regulation of gluco-homeostasis.

Absorbed nutrients stimulate D-cell somatostatin and Acell glucagon activity. Increased glucose and amino acids stimulate B-cells (insulin) whereas glucose depresses Acells (glucagon). F-cells (pancreatic peptides) are stimulated by cholecystokinin, secretin, gastrin and absorbed amino acids. In summary, A-cells stimulate B- and Dcells; D-cells inhibit A-, B- and F-cells. Pancreatic polypeptides from the F-cells are glycogenolytic without producing hyperglycemia. They also act to lower plasma glycerol, cholesterol, fatty acids and apolipoproteins, while increasing triglyceride levels. 105 Pancreatic polypeptides inhibit gut motility and gut, exocrine pancreatic

and gallbladder secretions. They also are antilipolytic and induce satiety via the central nervous system.55

EXOCRINE

Exocrine pancreatic secretions include trypsinogen, chymotrypsinogen, trypsin inhibitor, procarboxypeptidase, amylase and lipase. These enzymes are released into the duodenum and, along with gut peptides, further digestion. Trypsinogen and chymotrypsinogen are secreted in an inactive form so as not to induce autodigestion. Enterokinase from the gut activates trypsinogen to trypsin. Trypsin, in turn, cleaves chymotrypsinogen to chymotrypsin.

Factors influencing exocrine pancreatic enzyme secretion include the following: feeding, distention of the proventriculus with peptones, gastrin-releasing peptides, increased cholecystokinin, vasoactive intestinal peptide, neurotensin, secretin, hydrochloric acid, vagus innervation and cholinergic agents. 23,59,74,100,118

Cholecystokinin influences the enzymatic content of pancreatic secretions except amylase.34,86 Secretin, and to a larger extent vasoactive intestinal peptide, increase the aqueous component of pancreatic juices. Neurotensin increases lipase and depresses amylase secretion. Ingestion of lipids causes neurotensin release from intestinal stores.33 Diets rich in carbohydrates increase amylase, fats increase lipase, and protein increases chymotrypsin activity in pancreatic secretions. 19,64 The release of some of the islet hormones occurs before nutrients are even absorbed into the bloodstream, allowing for rapid adjustments to maintain homeostasis.

Exocrine Pancreatic Insufficiency

Exocrine pancreatic insufficiency in birds has been suggested by the observation of undigested food in the feces, voluminous foul-smelling droppings, weight loss and failure to thrive. With many cases of psittacine proventricular dilation presenting similarly, appropriate biopsies may be indicated to assist in diagnosis. Pancreatic insufficiency has been reported as a secondary effect of a pancreatic adenocarcinoma.98 This yellow-naped Amazon (Amazona ochrocephala auropalliata) was presented with a 3-month history of weight loss and voluminous foul-smelling droppings. Confirmation of pancreatic insufficiency was made from fecal tests positive for neutral and split fats and negative for trypsin. In addition, no elevation in blood triglyceride levels occurred with oral corn oil administration until the oil was mixed with pancreatic enzymes. The pancreatic adenocarcinoma was found on necropsy.98

Another case in a macaw was reported with feces containing starch and fat. The bird's feces returned to normal with the addition of trypsin to the food. When trypsin was discontinued 6 weeks later, the feces remained normal. 90 A slightly acidic diet rich in peptones should increase pancreatic exocrine secretions. This may prove a useful therapeutic adjunct to the addition of pancreatic enzymes to the food.

Diabetes Mellitus and Pancreatitis

In most granivorous birds, hyperglycemia occurs with normal insulin and increased glucagon levels, however, some birds have been documented with low insulin levels. 90 Clinical signs attributable to hyperglycemia are severe polyuria, polydipsia, increased appetite, and weight loss.90 Often there is a history of obesity and poor nutrition. Hyperglycemia may be secondary to other diseases and often resolves when the underlying disease is treated. Hyperglycemia in obese psittacines has responded to low-fat diets and weight loss. Obese Quaker parakeets (Myiopsitta monachus) have been found to have pancreatic necrosis.71 Those that survive have pancreatic insufficiency. A number of viruses, such as herpes, pox and polyomavirus, may cause pancreatic pathology.⁴² Birds on certain drugs (eg, medroxyprogesterone) have shown signs of hyperglycemia.

It has been suggested that an amylase greater than 2000 IU/L is diagnostic for pancreatitis. Lower values of amylase may be more indicative of renal disease. Chronic stress causes chronic hyperglycemia with increased insulin levels and resultant insulin resistance. To evaluate a bird with hyperglycemia it is important to keep environmental stressors to a minimum. Evaluating the home situation and diet may indicate stress and/or nutritional issues. If possible, glucagon, insulin and amylase should be evaluated along with evidence of persistent hyperglycemia. A urine dipstick in normal birds usually demonstrates negative or trace glucose. Radiographs and fecal Gram's stains may aid in the search for any underlying diseases.

Treatment

If insulin levels are depressed, the bird may respond to exogenous insulin. Insulin protocols are extrapolated from other species and are carried out in much the same way as in mammals. Somatostatin was tried in a sulfurbreasted toucan (*Ramphastus sulfuratus*) at 3 μ g/kg SC BID. The bird improved clinically, but died acutely after 4 months. The body was not presented for necropsy. During therapy, the bird maintained high glucose (>1300 mg/dl) and glucagon (>3100 pg/ml) levels. It would be interesting to evaluate higher doses of somatostatin.⁷¹ If glucagon is elevated, it would be interesting to try antiglucagon serum. When anti-insulin serum was used in chickens, glucose became extremely elevated.¹⁰⁷

Oral medications may have promise. Glipizide, a drug that increases insulin release from β -cells, has been used successfully in some cases at 1 mg/kg PO BID (Echols, personal communication). Other oral medications that may be tried include thiazolidinediones, which enhance peripheral insulin sensitivity, and α glucosidase inhibitors, which delay glucose absorption from the gut. Chicks with dexamethasone-induced hypocorticalism demonstrated increased insulin sensitivity and attenuated glucagon responsiveness. ⁷⁰

Pineal Gland

The pineal gland is made of ependymal cells, photoreceptor-like cells and neurons.17 The gland is located between the two hemispheres of the telencephalon and the cerebellum. This gland's photoreceptive-like cells are stimulated by light through pinopsen, a pineal-specific photoreceptive molecule, making the pineal a major component of the circadian pacemaking system. 91,117 The pineal's rhythmic synthesis and secretion of melatonin is regulated by neural signals from sympathetic nerves. 92 A second component of the circadian pacemaking system consists of a self-sustained oscillator, which is an area of the hypothalamic region possibly equivalent to the mammalian suprachiasmatic nuclei. The third component, at least in some galliforms and columbiforms, are the retinae of the eyes. 50,117 These three components work in concert to stabilize and amplify a self-sustaining circadian output. Light is the most powerful stimulus for the circadian rhythm and also can affect the system via the extraretinal/extrapineal photoreceptors located deep in the brain (Fig 19.6).117 The relative contribution each part plays in keeping the rhythm differs between species and, at times, within the same individual. The predominant factor maintaining rhythm in the house sparrow is the pineal gland, in the pigeon it is both eyes and pineal gland, and in the Japanese quail it is the eyes.

Changes in the pacemaker are partly related to the rhythmic synthesis and release of melatonin. These changes may be important in environmental situations, such as mid-winter and summer in the high arctic where conditions are constant, and also in the ever-changing conditions encountered during migration. In arctic mid-winter and mid-summer birds, and in migratory birds, there is a reduction in melatonin amplitudes. This reduction should result in a reduction in the degree of oscillation of the pacemaking system. A reduction in oscillation reduces the overall output of the pacemaker. This should facilitate adjustments to altered environmental conditions during migration, and in conditions that are more constant, it may enhance entrainability to weak Zeitgeber influences. In the should result in the same constant, it may enhance entrainability to weak Zeitgeber influences.

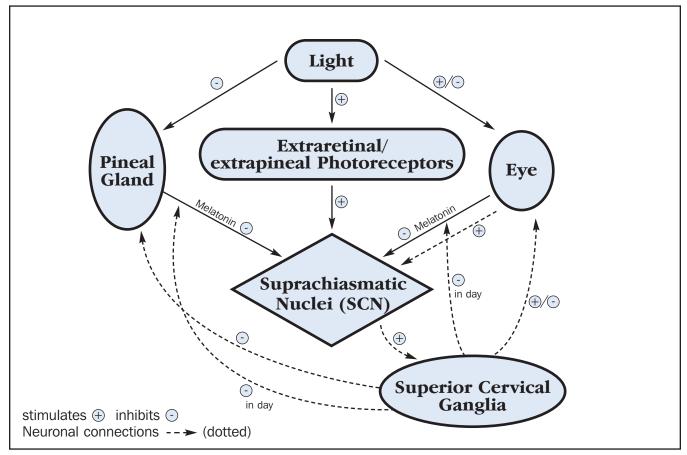

Fig 19.6 | Interactions of the Circadian Pacemaking System

Sometimes in constant conditions, the pacemakers are unable to sustain the persistent rhythm without periodic melatonin input from the eyes or pineal gland, or periodic neural input from the suprachiasmatic nuclei. 117 The most powerful stimuli of synchronization of the circadian rhythm is periodic alteration of light intensity. 2 Light affects melatonin synthesis by entrainment of circadian melatonin rhythms and acute inhibition of melatonin synthesis. 36 Light inhibition of melatonin causes sleep impairment in pigeons. 14

Retinal photoreceptors appear to mediate light-induced suppression and photic entrainment in pigeons and Japanese quail.³⁶ Dopamine stimulates retinal melatonin synthesis. Dopamine has shown to have a rhythm of release opposite to melatonin, that is, increased levels in the day and decreased levels at night. Experiments have demonstrated that the interaction of dopamine and melatonin are necessary for maintaining the anti-phase relationship between the two rhythms.³⁶

Melatonin also affects regulation of seasonal changes in immune function by enhancing cell-mediated immunity.¹¹ As discussed in the Song section in this chapter, melatonin also inhibits the neural plasticity of the song control system.^{12,13,36} These seasonal regulations and the action of melatonin appear to be modified by the same

central thyroid-dependent mechanism that controls the reproductive state in birds.¹¹

Melatonin helps to time migration and the hatching of eggs, but does not fully coordinate reproductive activity with a favorable time of year. In non-tropical birds, photoperiod is the predominant proximate factor. With increasing photoperiod in the spring, secretion of luteinizing hormone releasing hormone (LHRH) increases and results in gonadal maturation. Breeding terminates while days are still long, due to induced photorefractoriness. The gonadal regression during this time is associated with a large decrease in LHRH. This suggests photoperiodic responses involve direct interactions between photoreceptors and LHRH neurons. In

Melatonin synthesis also has been demonstrated in Harderian glands, the gastrointestinal tract and retina. The extrapineal melatonin is only rarely released into the circulatory system. Presumably, it exerts its influence locally. 51.63 High concentrations of melatonin are found in enterochromaffin cells of the mucosal epithelium of the gastrointestinal tract. 63 Pinealectomized pigeons were found to have a 24-hour cycle of melatonin secretion in the gastrointestinal tract, with levels increased at night and decreased during the day. 63 Melatonin receptors have been found in a variety of tissues, which suggests

direct actions of melatonin on the function of different organ systems in response to internal and external stimuli. 102

With the complex responses seen in birds due to duration and intensity of light, it seems paramount that the bird's natural photoperiod be accommodated. This is true for the home environment as well as the hospital. Night treatments should be done quickly, with an attempt not to shine light toward the head, because even a short duration of light exposure in the night can throw the natural circadian rhythm off. In 24-hour clinics, it is important to keep cages covered during the normal night duration.

THERMOGENESIS

The pineal gland influences thermoregulation. Pinealectomy performed on some species caused increased core body temperature and decreased tolerance to heat at night. This effect returns to normal with the administration of melatonin. Exogenous melatonin in intact house sparrows decreased core body temperature by 4.7°C within 30 minutes. Helatonin may be an effective antipyretic. Melatonin facilitates sleep and acts to synchronize the decrease in body temperature and metabolic rate in order to reduce energy expenditure during inactive periods. Helatonin facilitates are spenditure during inactive periods.

Another area of the brain that is involved in thermogenesis is the preoptic/anterior hypothalamic area (PO/AH) where warm- and cold-responsive neurons are found.32 A number of neuroactive compounds have demonstrated effects in this area. When acetylcholine, dopamine, serotonin or norepinephrine were injected into the PO/AH of pigeons, the birds demonstrated peripheral vasodilation, inhibition of shivering and decreases in heat production.58 Prostaglandin E2 injected into the hypothalamus caused hyperthermia in pigeons and fowl, whereas prostaglandin F_{2a} caused hypothermia in fowl and hyperthermia in pigeons.87 Arginine vasotocin reduces shivering, body temperature and oxygen consumption, whereas angiotensin-II has the opposite effects.54 Thyroid hormones help to adjust the body temperature in response to the environment by increasing T₃ levels in cold and decreasing T₃ levels in warm surroundings.²⁶ This information implies that the hypothalamus is more an integrator of physiological inputs than a direct controller of thermogenesis.

It is clear that, under most situations, when a clinician is faced with a "sick" bird (excluding head trauma), keeping it warm is very important. If prostaglandins are administered to the bird or the bird's photoperiod is rearranged at this time, it would be prudent to monitor for changes in the patient's body temperature.

Song

Over the last decade, there has been an increased interest in the effects of hormones on behavior and changes in brain morphology. The complex learned behavior of singing is expressed differently in the different sexes of many species of birds. The current research suggests that steroid hormones can induce a neuroplasticity, which activates this behavior. This seasonal neuroplasticity is more dramatic in birds than in other vertebrates.

In many song birds, most notably the zebra finches (*Taniopygia guttata*) and canaries (*Serinus canaria*), a song control system (SCS) has been identified in the brain. The higher vocal center, a part of this system, appears to be unique to the songbird suborder. ^{4,21,88} This center is implicated in the learning of new song, as well as the production and perception of previously learned songs. ^{21,88} Several of the nuclei of the SCS contain high levels of androgen, estrogen, norepinephrine, and acetylcholine muscarinic and dopamine receptors along with acetylcholinesterase. ⁹⁹ In addition, fibers containing neurotransmitters (catecholamines), or neuropeptides (vasoactive intestinal polypeptide, enkephalin, cholecystokinin, substance P and Metenkephalin) are present. ^{4,8,9}

Estrogenic metabolites of testosterone increase norepinephrine and dopamine turnover in the SCS, suggesting an interaction between the metabolites of testosterone and these catecholamines. 8.9 Androgen receptors in the SCS appear to be unique to song birds and the Anna's hummingbird (*Calypte anna*), a non-song bird. 38

In the fall, when singing is not done to attract a mate, daylight is decreasing and sex hormone levels are low. In the song sparrow (Melospiza melodia), evidence suggests that the autumnal singing involves estrogen acting locally in the brain. The source of the neuroactive estrogen is unknown, but does not appear to be from testosterone of gonadal origin. 110 The administration of testosterone will increase song rate, whereas castration will reduce, but not always eliminate, male-typical song, depending on the species.1 Castrated song sparrows in the wild sang at effective rates when territorial challenges occurred. 125 Testosterone influences song quality. 80 Studies indicate that it is the androgenic and estrogenic metabolites of testosterone, through testosterone's aromatization, that are required to completely restore the full rate of singing.⁵² It appears that in zebra finches, estrogenic metabolites of testosterone selectively promote courtship song.121

Temperate zone wild male songbirds have seasonal peaks of testosterone associated with increasing daylight in the spring. At this time, increases in the volume of song control nuclei occur. 108,109 The song control nuclei

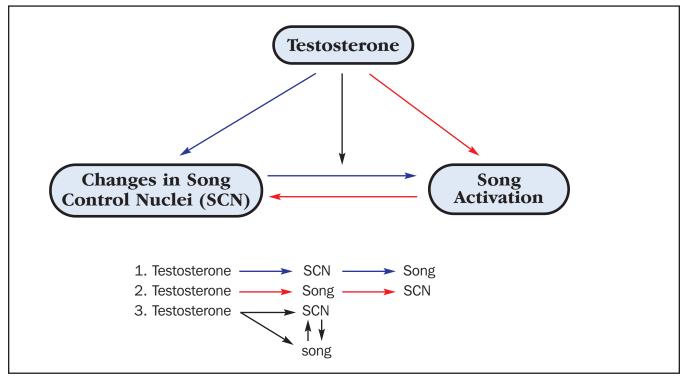

Fig 19.7 | Song Activation Models.

volume increase precedes the growth and development of the reproductive system. ¹¹⁶ Other environmental stimuli clearly play a role. Starlings in captivity, exposed to spring photoperiods, increased the volume of higher vocal center nuclei of the SCS, whereas males kept in outdoor aviaries in the spring had volume increases in the nuclei of most, if not all of the SCS. ¹⁰ It is possible that seasonal variation and/or steroid-induced changes in catecholaminergic afferent input into the SCS are important in regulating changes in the vocal learning or production of song, as well as the volume changes in nuclei of the SCS.

A significant amount of research indicates the importance of testosterone on the morphology of the SCS.

Testosterone can restore SCS development in castrated males, corresponding to photoperiod changes in both gonad and SCS size. 1.108,109 Testosterone given to females results in male-typical song behavior and increase in the size of their song control systems. 5.115 There also is evidence that the SCS can grow in response to photoperiods independent of testosterone. Recent data indicate that the volume of SCS nuclei correlates with song performance in some cases. It may be that high rates of singing could cause an increase in the SCS. Brain-derived neurotrophic factor that promotes growth of the higher vocal center is released by singing activity. This information helps to

explain the dissociation sometimes observed between steroid-induced and seasonal changes in the song system morphology and vocal behavior (Fig 19.7).

Melatonin also may play a role in song system morphology changes. The volume of the song control nuclei was studied in castrated starlings held under different photoperiods to induce reproductive states characteristic of different seasons. Long days are associated with larger volumes of the higher vocal center nuclei than are short days. Melatonin administration attenuated the long day-induced volume increases. The song system also was found to have high densities of melatonin receptors. Long durations of melatonin secretion in late fall and winter subdue the effects of testosterone. With long days, melatonin secretion decreases rapidly and testosterone increases. It is apparent that the interaction between many hormones may fine-tune the activity of the SCS.

The SCS and behavior that induces singing are extremely complex. Before administering hormones to induce singing, it is imperative that we learn more about this system. More importantly, good nutrition and a good environment will allow the bird to sing when it is appropriate. A quiet bird out of breeding season may be a happy bird, with no need for male aggressive or territorial singing. Conversely, compulsive singing may be a sign of stress.

Section II: A Retrospective Study of Case

Submissions to a Specialty Diagnostic Service

Overview of Tumors: Section I

Clinical Avian Neoplasia and Oncology

TERESA L. LIGHTFOOT, DVM, Dipl ABVP-Avian

Avian neoplasias encountered in practice include cancer of the skin, oral cavity, sinuses, liver, kidney, reproductive organs, bones, brain, vascular structures and connective tissue. External tumors may be detected by physical examination and can often be diagnosed by needle aspiration, wedge, punch or surgical biopsy. Internal neoplasias often require radiographs, ultrasound, endoscopy, and biopsy or exploratory surgery to identify, diagnose and determine the extent of the neoplastic processes.

Treatment of neoplastic processes in birds is poorly documented. Most reports of treatment protocols are either anecdotal or involve a single patient. Many reports are not published, but are to be found in avian veterinary discussion groups on the Internet.^{35,36,37}

The presentation in this text of these anecdotal treatments is problematic. Failure to include preliminary information regarding efficacy and/or clinical response may reduce the practitioner's willingness and ability to recommend treatment. However, future studies may either reinforce these experimental protocols or they may demonstrate a lack of efficacy or serious side effects of these regimes. The ultimate decision will lie with the knowledgeable practitioner and the well-informed client.

To date, the treatment of avian neoplasia has mirrored treatment in other domestic species. Generally, solid tumors are best treated with surgical excision, while systemic neoplastic processes (ie, systemic lymphoma, metastatic conditions) are most effectively managed with use of systemic chemotherapy. Cases in which surgical excision is incomplete or impossible may benefit from alternative forms of local therapy, including external beam radiation (Cobalt 60 or linear accelerator), cryotherapy, photodynamic therapy or hand-held radiation applicators.

CUTANEOUS MASSES

These may be pseudo-neoplastic conditions such as xanthomas and lipomas, or neoplastic lesions.

Xanthomas

These are generally friable, yellow-colored, fatty-appearing masses that may be located anywhere on the body, but are often seen on the distal wing, in the sternopubic area and on the keel (see Chapter 13, Integument). The origin of xanthomas is unknown, however, dietary improvement, including sufficient vitamin A or vitamin A precursors, has been noted to be curative in less advanced cases. Xanthomas tend to be very vascular and surgical excision, when necessary, should be undertaken with due attention to hemostasis. Diffuse xanthomas may be amenable to cryotherapy, but attention must be paid to maintenance of the vascular supply.³⁵

Lipomas

These occur most frequently in budgerigars and are usually located on the keel or in the sterno pubic area. Most early lipomas respond to modified diet therapy. Lipomas that cause clinical signs can be addressed via surgical excision. Malignant liposarcomas are rare in psittacines.³³

Mucoepidermoid Carcinomas

Mucoepidermoid carcinomas are rarely reported in birds. In humans, these tumors demonstrate variable degrees of malignancy and surgical resection is often curative. Comparable grading of this type of neoplasia has not been established in the avian patient (Figs 20.1.1, 20.1.2).

Fibrosarcomas

These can occur anywhere on the body, but are most commonly seen in the oral cavity, associated with long bones, or in the abdominal cavity (Figs 20.1.3, 20.1.4).

Fig 20.1.1 | Mucoepidermoid carcinoma.

Fig 20.1.2 | Mucoepidermoid carcinoma after resection.

Fig 20.1.3 | Fibrosarcoma on the face of a budgerigar.

Fig 20.1.4 | Fibrosarcoma on the wing of a lovebird.

Fig 20.1.5 | Squamous cell carcinoma of the rhamphotheca, and papillomatosis in an older Timneh grey parrot.

Fibrosarcomas may be subcutaneous or more deeply located in underlying tissue, and often appear fixed and proliferative with a nodular, red surface. They tend to be locally invasive and often recur with conservative surgical excision. Therefore, additional local treatment in the form of radiation therapy is often indicated for providing long-term local control. As the metastatic rate in other domestic species ranges from 5 to 15%, local disease management is paramount, with metastatic control as a secondary concern. Surgical excision followed by both radiation and chemotherapy has been reported with some success in a few publications. Strontium radiation therapy, although limited by depth of penetration, has been anecdotally reported as efficacious in several instances.

Squamous Cell Carcinomas

These also may occur anywhere on the body, being most prevalent at mucocutaneous junctions of the head (Fig 20.1.5), on the distal wing and on the phalanges. The uropygial (preen) gland also may develop either adenocarcinoma or squamous cell carcinoma. (Note that *Amazona* spp. do not possess a preen gland). Squamous cell carcinomas tend to be extremely locally invasive and

complete excision is rarely accomplished. Radiation therapy has been attempted with some success, however, squamous cell carcinoma appears to be an exceptionally radioresistant tumor and long-term control is rare. Anecdotal reports indicate that radioresistance may be even greater in birds than in mammals. 19,35 Strontium therapy when tumor depth is not a limiting factor has shown some promise in selected psittacine cases.35 Distant metastasis is rare, therefore chemotherapy is not commonly utilized. Photodynamic therapy (PDT) has been attempted in two reported cases. One case of a squamous cell carcinoma in the beak of a hornbill showed a positive result in decreasing tumor size, but failure to eliminate the neoplasia.31 The second case demonstrated a positive response to PDT after each treatment, but treatments were not able to be administered at regular intervals.28

NEOPLASIA OCCURRING IN THE MUSCULOSKELETAL SYSTEM

Theoretically these include the benign lesions such as chondroma and hemangioma, and malignant tumors including osteosarcoma, chondrosarcoma and leiomyosarcoma. Wide surgical resection or amputation are

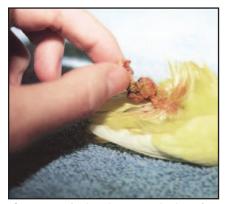

Fig 20.1.6 | Chondroma on the leg of a budgerigar.

Fig 20.1.7 | Gross appearance of the abdomen in a 9-month-old African grey parrot with diffuse coelomic hemangioma.

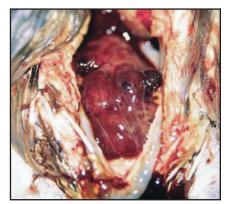

Fig 20.1.8 | The bird in Fig 20.1.11, showing hemangioma encompassing most abdominal viscera.

generally the suggested methods of treatment, as benign lesions are often cured with complete excision and a decrease in tumor burden can be accomplished in malignant lesions. As tumors such as osteosarcoma carry high metastatic rates, additional therapies may be indicated. Extrapolation from canine and feline oncology may suggest other modalities such as radiation therapy for additional local treatment and chemotherapy for systemic control.

Chondromas

Therapy for chondromas generally involves aggressive surgical excision of the affected area (Fig 20.1.6). Radiation and chemotherapy may be considered.

Osteosarcoma

Confirmation of osteosarcoma has rarely been reported in psittacines. Species and anatomic location predilections have not been noted in psittacines. Documentation of classifiable radiographic changes consistent with osteosarcoma is not available for birds.

A biopsy should be obtained from patients where radiographic bony lesions are present. Under inhalant anesthesia, a 22- to 20-gauge needle can be surgically introduced into the bone. A sufficient sample is usually obtained and subsequently retained in the hub of the needle. The sample can then be dislodged with smaller gauge wire and submitted. If a diagnosis of osteosarcoma is received, amputation with follow-up chemotherapy is the current recommended protocol extrapolated from canine medicine.

INTERNAL NEOPLASIA

Hemangiomas

These seem to occur more commonly than hemangiosarcomas in birds. Hemangioma may be internal or external and commonly appears as a red-purple, flat, firm lesion

(see Chapter 13, Integument). Although histopathologically benign, in at least one case in this author's experience, hemangioma occurred in a juvenile African grey (Psittacus erithacus) and involved the coelomic cavity, small intestine, liver, lung, air sacs and pericardium. Complete surgical excision could not be accomplished and euthanasia was eventually required (Figs 20.1.7, 20.1.8). Treatment of a hemangiosarcoma with radiation therapy has been reported in one case.9

Internal Carcinomas

These are commonly reported in birds and include ovarian neoplasias (of various cell origins), renal carcinomas, hepatic adenocarcinoma, hepatobiliary and pancreatic adenocarcinoma (related to papillomas in Amazons), splenic and gastric carcinomas. Papillary carcinomas of air sac origin are locally invasive and may present as external masses. Anecdotal reports exist indicating intralesional carboplatin therapy may be useful in ovarian and renal adenocarcinoma, generally following surgical debulking and confirmation of the neoplasia on histopathology. 18,34 Bile duct carcinoma also has been treated with carboplatin successfully in one report.³⁸ Toxicity studies with cisplatin in cockatoos indicate that psittacine tolerance for this drug may be greater than that of mammals.8

Tamoxifen administration has not been evaluated for efficacy in cases of avian ovarian carcinoma, but anti-estrogenic activity was suggested and side effects were minimal in one drug trial.¹⁷ GnRH agonists^a have been effective empirically (dosed at 200-800 µg/kg), however, confirmation of neoplasia (as opposed to cystic ovarian disease) has not often been confirmed prior to therapy. 16,20

Doxorubicin (adriamycin) is commonly employed in the treatment of carcinomas in human and canine patients. The limiting toxic effects of doxorubicin include myelosuppression and cardiac toxicity. To date, the degree to

which these concerns will apply to avian cancer patients has not been determined. Anecdotal reports of both toxicity and efficacy of doxorubicin in avian patients are currently inconclusive.³⁴ Dosages of 50-60 mg/m² have been used with no adverse reactions. In several cases there has been significant tumor regression (Goldsmith, Lightfoot, unpublished data, 2004).

Carcinomas, generally diagnosed at necropsy, are often found at the proventricular-ventricular junction. Death from this neoplasia may be due to hemorrhage, perforation and sepsis or endotoxic shock, or inanition and subsequent wasting. Metastasis to the lungs has been confirmed in one case report.⁴

Biliary and pancreatic carcinomas are frequently diagnosed in the genus *Amazona* and to a lesser degree, *Ara*, in conjunction with internal papillomatosis. ^{11,13} A recent connection to a herpesvirus has been identified (see Chapter 32, Implications of Viruses in Clinical Disorders). Carboplatin has been used in several cases with equivocal results, but with no apparent toxicity. ^{7,35,38}

Surgical excision is the treatment of choice with solitary lesions of hepatic cell carcinoma in other species, and is the only documented curative treatment in human medicine. Combinations of chemotherapy and radiation therapy have been used with equivocal results in people in an attempt to prevent or limit metastatic disease. In widely disseminated hepatic carcinoma, palliative chemotherapy is often employed. However, extrapolation from people would indicate that this type of cancer is highly resistant to chemotherapy. The most commonly employed chemotherapeutic agents in human medicine appear to be doxorubicin and 5-fluorouracil (5-FU), however, mean survival times do not appear to be statistically improved in patients with widely disseminated disease. The use of immunotherapy — including interferon, in conjunction with cisplatin, doxorubicin and 5-FU — has shown the most promise to date in human patients. Unfortunately, interferon is limited in its usefulness by cost and availability in veterinary medicine. The efficiency of radiation therapy for carcinomas and other neoplasias is largely unknown. However, tolerance of radiation therapy has been anecdotally reported as greater than anticipated.

Endocrine Neoplasia

Neoplasia of endocrine origin is not frequently reported in birds.

Pituitary Adenomas

These have been documented in multiple avian species, but are most prevalent in budgerigars and cockatiels. Affected animals may present with acute neurologic conditions (seizures/opisthotonos). They also may present

Fig 20.1.9 | Thymoma in a lovebird, intraoperatively.

with conditions related to the pituitary hormone(s) that are affected. Usually, this will be pronounced polydypsia and polyuria. Occasional presentations will be that of a retrobulbar mass and subsequent exophthalmia.²⁷ In human medicine, surgical resection and radiation therapy (if needed) are utilized for treatment. Size and monetary constraints make routine treatment by these methods unlikely in our small psittacine patients.

Thyroid

Budgerigars that are iodine deficient may develop nonneoplastic thyroid hyperplasia that presents as a thyroid mass, often causing a change in the voice or a respiratory squeak.

Thyroid Tumors

These are not as common in birds as they are in domestic rabbits, but do occur (Fig 20.1.9). They may be intrathoracic or located in the area of the neck. In humans, classification according to cell type (medullary, cortical and mixed) is a prognostic indicator, with cortical tumors having the highest incidence of recurrence and malignancy. Thymoma and thyroid adenocarcinoma have been reported in several psittacine species. Surgical excision is the primary treatment recommendation. Adjuvant radiation and chemotherapy protocols are being utilized in human medicine. Cisplatin is used in many human chemotherapy protocols for thymomas and thymic carcinomas. Limited studies have shown that psittacines may be tolerant of the common side effects induced by cisplatin, and this agent may be useful in the treatment of these neoplasias.

Pancreatic Neoplasias

Infrequent accounts of primary pancreatic neoplasia of variable cell origin, not associated with internal papillomatosis, have been reported.²⁵

Fig 20.1.10 | Retrobulbar lymphoma in a young African grey.

Fig 20.1.11 | Gross necropsy photo of the liver from the African grey in Fig 20.1.10. A fine-needle aspirate of the liver demonstrated that the lymphoma had spread to involve the hepatic parenchyma.

Respiratory Neoplasia

Primary respiratory neoplasia is uncommon in psittacines. ¹² An exception seems to be an intrathoracic neoplasia reported in cockatiels. It is characterized by the inclusion of two cell types, having both mesenchymal and epithelial cell components (see Section II of this chapter). Few other primary pulmonary neoplasias have been reported in the literature. ² Metastatic pulmonary neoplasia may occur, but it is not noted with the same frequency as is documented in dogs. ⁴

Lymphoma/Lymphosarcoma

Numerous reports of exophthalmos in psittacines, particularly young African greys, have been diagnosed as retrobulbar lymphoma (Fig 20.1.10). Differential diagnoses for this condition are pituitary adenoma and hyperplasia or adenoma of the Harderian gland. Lymphoma may have many presentations in pet birds, much as it does in other companion animals (Fig 20.1.11). Chemotherapy is the treatment of choice for systemic disease, and surgery and radiation therapies have been successfully employed in cases of solitary lymphoma. ^{6,35} To date, no evidence of retroviral activity has been associated with psittacine lymphoma.

The clinician may find it useful to have access to current protocols for lymphoma that are utilized in canine medicine. Tracy LaDue, Diplomate ACVIM-Oncology and ACVR-Radiation Oncology, of Florida Veterinary Specialists in Tampa, Florida, US, has generously provided the following abbreviated outline of therapeutic options and chemotherapeutic agents. These protocols are NOT established for avian patients, but are provided to give the practitioner a point of reference when attempting to design potential therapeutic regimes for birds with lymphoma. Again, species differences in response may well

exist. Some of the chemotherapeutic agents listed may be determined to be either ineffectual or contraindicated in birds. As documentation of these variables occurs, it is hoped that protocols can be developed that will produce more predictable results in the avian patient.

Chemotherapy Protocols for Canine Lymphoma*

(Current recommended canine dosages can be found in Plumb's Veterinary Handbook).

- 1. Oral Therapies
 - a. Prednisolone and cyclophosphamide
 - b. Lomustine (CCNU)
- 2. Injectable Therapy
 - a. COP-L Protocol
 - i. L-asparaginase injection
 - ii. Oral prednisolone (tapering dose)
 - iii. Oral weekly cyclophosphamide
 - iv. Vincristine injections weekly IV
 - b. Single-agent adriamycin injections q 3 weeks IV
 - c. UW-Madison Cyclic Combination
 - i. L-asparaginase
 - ii. Vincristine
 - iii. Cyclophosphamide
 - iv. Adriamycin
 - v. Prednisolone

Applicable testing (CBC, biochemistries, cardiac evaluation) should be performed to assess the initial and intratherapeutic health of the patient.

*It must be emphasized again that these protocols are designed for *canine* patients. Extrapolation to avian patients must be undertaken with the knowledge that efficacy and potential side effects have not been documented.

CHEMOTHERAPEUTIC AGENTS

Anticancer agents are typically broken into six categories based on their mechanism of action.

- 1. Alkylating agents such as cyclophosphamide and lomustine prevent cell replication by covalently binding to the nucleotide bases of the DNA molecule.
- Antimetabolites will mimic purine, pyrimidine or metabolite precursors of the nucleotide bases, resulting in non-functional DNA.
- 3. Steroids such as prednisone and prednisolone cause lympholysis and suppress neutrophil function and antibody production.
- 4. Plant alkaloids such as vincristine bind to microtubules to prevent normal formation and function of the mitotic spindle. The antibiotics such as adriamycin intercalate between DNA base pairs to disrupt transcription and also cause oxygen free radical damage.
- 5. Miscellaneous drugs such as the Platinol compounds (cisplatin and carboplatin) also bind to bases of the DNA preventing replication, but have a bifunctional ability with double attachment to DNA strands.
- L-asparaginase hydrolyzes asparagine to aspartic acid and ammonia, resulting in loss of an essential amino acid for cell function.

Most anticancer agents have associated vomiting, diarrhea and bone marrow suppression as sequelae. It is important to monitor patients for signs of dehydration or secondary infection as a result of chemotherapy administration. Some anticancer agents have particular toxicities known to that drug alone, such as sterile hemorrhagic cystitis due to cyclophosphamide metabolites in dogs and people. Such toxicities are not well reported in avian species and should be monitored for accordingly.

When confronted with a confirmed diagnosis of neoplasia, a current literature search is warranted due to the rapid advances and changes in treatment recommendations. Consultation with a veterinary oncologist will increase the likelihood of selecting an appropriate treatment regime and properly administering the chosen therapy.

Overview of Tumors: Section II

A Retrospective Study of Case Submissions to a Specialty Diagnostic Service

MICHAEL M. GARNER, DVM, Dipl ACVP

The occurrence of various types of avian neoplasia has been comprehensively reviewed.⁶ This section documents the prevalence of neoplasms in 22 avian orders submitted to a specialty diagnostic service (Northwest ZooPath, Monroe, WA) from 1994 to 2002. Cases were selected based on histologic diagnosis. Cysts, hyperplastic processes, fibromatous polyps and poxvirus-related proliferative lesions were not included. Cases diagnosed as neoplastic based on cytology alone also were excluded. Although potentially reversible and not considered true neoplasms, adenomatous polyps and papillomas were included because of the known association of these lesions with concurrent neoplasia in psittacine birds.4 Type, location, biological behavior and patient outcome are addressed. Apparent trends for particular types of neoplasms in some orders or species also are identified and discussed. For the purposes of this manuscript, prevalence refers to a given percentage within the study population, and the study population comprises the cases submitted to the service. The prevalence of these neoplasms in the populations from which these birds originated is not known.

Table 20.2.1 lists the tumor submissions by site and biological behavior. Skin was the most common site for tumor development, followed by alimentary tract, reproductive tract and liver. In all locations except alimentary tract, malignant tumors were more common than benign tumors; the large numbers of cloacal and oral papillomas and adenomatous polyps in psittacine birds account for this variation in behavior.

Table 20.2.2 summarizes total numbers of submissions and total numbers of tumors for each order. For the study period, 9574 avian samples were submitted, representing 22 orders; 557 neoplastic processes were identified, for an overall prevalence of 5.8%. The overall

prevalence of neoplasia over the 7-year period was highest in Anseriformes (ducks, geese, swans), Galliformes (poultry, pheasants), Strigiformes (owls) and Cuculiformes (cuckoos, turacos).

Tables 20.2.3 and 20.2.4 list the tumor submissions by type and biological behavior. The most common types of tumors were cutaneous squamous cell carcinoma, multicentric lymphoma, cutaneous soft tissue sarcoma, biliary adenocarcinoma and ovarian/oviduct adenocarcinoma.

Neoplasia by Avian Order

PSITTACIFORMES

Order Psittaciformes (parrots and related species) had 3545 representatives and 220 neoplastic processes (prevalence = 6.2%) (see Table 20.2.2), slightly higher than the average prevalence for tumor submissions from other orders. Table 20.2.5 summarizes the most common presentations of neoplasms within this order. Trend criteria were based on total number of tumor types in a species (two or more), and percent of total for all tumors in a species (10% or greater). Using these criteria, numerous trends were observed within this order. For cockatiels (Nymphicus hollandicus), trends were identified in soft tissue sarcoma, squamous cell carcinoma, ovarian/ oviduct adenocarcinoma, fibrosarcoma and seminoma. For Amazon parrots (Amazona spp.), trends were identified for squamous cell carcinoma, cloacal adenomatous polyp, cloacal papilloma and biliary adenocarcinoma. For macaws (Ara spp.), trends were identified for cloacal adenomatous polyp, cloacal papilloma and biliary adenocarcinoma. For cockatoos (Cacatua spp.), trends were identified for soft tissue sarcomas and cloacal adenomatous polyps. For budgerigars (Melopsittacus undulatus),

Table 20.2.5 | Prevalence of Most Common Types of Neoplasms in Psittacine Birds

Species and Total # of Tumors								
Tumor Type and % of Total Psittacine Cases (220)	Cockatiel (39)	Amazon (30)	Macaw (28)	Cockatoo (25)	Budgerigar (25)	Lovebird (19)	African Grey (8)	Rosella (3)
Soft tissue sarcoma - 23 (10.5%)	6 (15%)	0	2 (7%)	4 (16%)	4 (16%)	4 (21%)	1 (12.5%)	0
Squamous cell carcinoma - 22 (10%)	7 (18%)	3 (10%)	1 (4%)	0	5 (20%)	0	2 (25%)	2 (67%)
Cloacal adenomatous polyp - 15 (6.8%)	0	4 (13%)	4 (14%)	4 (16%)	0	0	1 (12.5%)	0
Ovarian/oviduct adenocarcinoma - 13 (5.9%)	7 (18%)	0	1 (4%)	2 (8%)	0	1 (5%)	0	0
Cloacal papilloma - 12 (5.5%)	0	4 (13%)	7 (25%)	0	0	0	1 (12.5%)	0
Fibrosarcoma - 11 (5%)	2 (5%)	0	0	2 (8%)	4 (16%)	2 (11%)	0	0
Biliary adenocarcinoma - 11 (5%)	0	4 (13%)	3 (11%)	0	0	1 (5%)	0	0
Lymphoma - 8 (3.6%)	0	2 (7%)	1 (4%)	0	1 (4%)	3 (16%)	1 (12.5%)	0
Seminoma - 7 (3.2%)	3 (7.6%)	0	1 (4%)	0	1 (4%)	0	0	0
Renal adenocarcinoma - 6 (2.7%)	0	0	1 (4%)	1 (4%)	4 (16%)	0	0	0

trends were identified for soft tissue sarcoma, squamous cell carcinoma, fibrosarcoma and renal adenocarcinoma. Interestingly, although lipomas are recognized as a common tumor in budgerigars, 6,12 a trend was not identified in this analysis of submissions. This may be because clinicians easily recognize these tumors, thus biopsies are not routinely submitted. For lovebirds (Agapornis spp.), trends were identified for soft tissue sarcoma, fibrosarcoma and lymphoma. For African greys (Psittacus erithacus) and rosellas (Platycercus spp.), trends were identified for squamous cell carcinoma.

Cloacal Adenomatous Polyps and Papillomas

Cloacal adenomatous polyps were common in Amazon parrots and macaws, and also were seen in cockatoos

(Cacatua spp.), an African grey, a thick-billed parrot (Rhynchopsitta pachyrhyncha) and a Patagonian conure (Cyanoliseus patagonus). This distribution is similar to that of retrospective studies of this condition. 4,14 Malignant transformation of cloacal "papillomas" has been described in psittacine birds.^{6,14} In this study, four cloacal adenomatous polyps (two macaws, one amazon parrot and one cockatoo) underwent local transformation to adenocarcinoma, although no metastases were seen. Adenomatous polyps also were noted in the proventriculus of a cockatoo and on the eyelid of a cockatiel. Two cloacal adenomatous polyps were associated with concurrent biliary adenocarcinoma and two with concurrent pancreatic adenocarcinoma. Cloacal papillomas also were common in macaws and Amazon parrots, and one

a. For all tumors represented two or more times in the study. Tumors represented only once not included.

b. Lymphoma is generally a multicentric process. In 35 birds, the tumor was considered multicentric rather than metastatic, based on the presence of neoplastic cells in at least two different tissue types. In only one dead bird with full tissue evaluation was lymphoma detected in only one tissue (thymus). The remaining four cases were single tissue biopsies that were lost to follow-up, but also were likely multicentric tumors. Two cases had apparent concurrent lymphoid leukemia, based on histologic evaluation.

c. Tumors were classified as soft tissue sarcomas if they were undifferentiated or had too much anaplasia to determine the cell of origin. Likely differentials were fibrosarcoma, leiomyosarcoma, rhabdomyosarcoma, synovial sarcoma, neurofibrosarcoma, myxosarcoma and amelanotic melanoma.

d. Intracoelomic myelolipomas were invasive and infiltrated many visceral tissues. It was difficult to determine if some visceral foci were extensions of the invasive process or represented metastatic lesions.

was seen in an African grey. Concurrent or isolated oral/choanal papillomas were occasionally seen. Only one of the cloacal papillomas was associated with concurrent biliary adenocarcinoma, and none were associated with malignant transformation in the cloaca.

Proliferative lesions of the cloacal mucosa of psittacine birds are well recognized. 4,6,14 Although typically referred to as papillomas, there are different morphologic presentations: a papilliform proliferation of squamous mucosal epithelial cells resembling a typical papilloma; and an adenomatous proliferation of glandular and villous mucosa more typical of a polyp, perhaps best termed an adenomatous polyp. Although the morphologic features of cloacal adenomatous polyps and papillomas differ, it is possible that these represent different morphologic variants of the same disease process. Both have similar site and species predilections, and both are sometimes associated with concurrent pancreatic and biliary malignancies. However, the distinction between cloacal adenomatous polyps and papillomas may not be purely academic. Based on this collection of the two cloacal phenotypes, the adenomatous polyps appear to have the most potential for undergoing malignant transformation in the cloaca, and for being associated with concurrent pancreatic or biliary neoplasia. Cloacal papillomas have been associated with herpesvirus gene sequences.5,13

Bimorphic Pulmonary Neoplasms of Cockatiels

Four separate cases of an unusual malignant pulmonary neoplasm were seen in cockatiels. The birds presented with a history of dyspnea and usually had a radiographically apparent mass in the thoracic region of the coelomic cavity. Microscopically, the tumor involved the lung and spread by extension to serosal surfaces of viscera, especially heart and air sacs. One case of possible metastasis to the endocardial surface also was seen. The tumor appeared to arise within the pulmonary parenchyma, around the parabronchi. These neoplasms have unusual cell morphology and are characterized by densely cellular sheets of round to elongate cells with large vesicular to amphophilic smudged nuclei. The cells stain positively for mammalian vimentin, a mesenchymal cell marker, and have cytoplasmic intermediate filaments consistent with vimentin, suggesting that the cells are of mesenchymal origin. The cells stain negatively for mammalian epithelial pan cytokeratins; however, desmosomes, a feature of epithelial cells, are occasionally seen between adjacent cells. The cell of origin is poorly understood, but the tumors appear to be "bimorphic" with mesenchymal and epithelial cell components. The nuclear characteristics of the neoplastic cells resemble the inclusions caused by polyomavirus, but no virus has been detected by electron microscopy, in situ hybridization or PCR (M.M. Garner, unpublished data).

GALLIFORMES

Order Galliformes (chickens, turkeys, pheasants, peafowl) had 783 representatives and 74 tumors (9.5%) (see Table 20.2.2), considerably higher than the average for tumor submissions from other orders. Table 20.2.6 summarizes the most common presentations of neoplasms within this order. Trend criteria were based on total number of a tumor type in a species (two or more), and percent of total for all tumors in a species (10% or greater). Using these criteria, numerous trends were observed within this order. For chickens, trends were identified for lymphoma, ovarian/oviduct adenocarcinoma and squamous cell carcinoma. These tumors are well recognized in poultry.^{2,10,11,16} Some of these tumors, particularly the lymphoid malignancies, may have been associated with or induced by viral infection. 2,10,11,16 The only identifiable trend in pheasants was for interrenal cell adenoma, an otherwise uncommon tumor in birds. For guinea fowl, trends were identified for squamous cell carcinoma, seminoma and hepatocellular carcinoma. The only trend identified in peafowl was lymphoma. For turkeys, trends were identified for ovarian/oviduct adenocarcinoma and lymphoma. Herpesviruses and retroviruses have been identified as important causes of neoplasia in gallinaceous birds, particularly chickens and turkeys, 2,10,11,16 and it is possible that viral oncogenesis was a factor in many of the cases within this order; however, serologic and other ancillary testing for viral causes was not routinely performed on case submissions, so viral status of affected birds was generally not known.

ANSERIFORMES

Order Anseriformes (ducks, geese, swans) had 1024 representatives and 119 tumors (11.6%) (see Table 20.2.2), considerably higher than the average for tumor submissions from other orders. All the birds were adults or aged and most tumors likely occurred spontaneously. Trend criteria were based on total number of a tumor type in a species (two or more), and percent of total for all tumors in a species (10% or greater). Using these criteria, only two trends were identified: lymphoma and biliary adenocarcinoma in ducks, although a broad spectrum of neoplastic processes was represented in this group.

PASSERIFORMES

Order Passeriformes (songbirds) had 1441 representatives and only 27 tumors (1.9%) (see Table 20.2.2), considerably below the average for other orders, suggesting that spontaneous neoplasia in passerine birds is relatively uncommon. All birds were adults, a broad spectrum of neoplastic processes was represented and tumors likely occurred spontaneously in most cases. One possible trend was observed: two mynahs had

Table 20.2.6 | Prevalence of Most Common Types of Neoplasms in Galliform Birds

a. Includes chickens, roosters, jungle fowl

hepatic malignancies and concurrent hemochromatosis, suggesting iron storage in the liver may precipitate malignant transformation in this species, as alluded to by other authors.8,9

PHOENICOPTERIDAE

Suborder Phoenicopteridae (flamingos) had 265 representatives and 13 tumors (4.9%) (see Table 20.2.2), suggesting that the overall prevalence of neoplasia in the family/suborder is about average. Interestingly, liver tumors accounted for slightly less than half of the tumor submissions (see Table 20.2.1), suggesting that hepatic neoplasia may be over-represented in captive flamingos. These birds typically store large amounts of iron in the liver^{7,15} and all the flamingos with hepatic neoplasia in this study had iron deposition; however, no overt changes were noted morphologically in relation to the iron, such as cirrhosis seen in mynahs, toucans or birds of paradise, 3,7,15 so the significance of the iron deposition relative to the neoplasia is undetermined. Two flamingos had squamous cell carcinomas on the pads of the feet, and had previous and ongoing protracted episodes of bumblefoot, which may have predisposed to neoplastic transformation.

STRIGIFORMES

Order Strigiformes (owls) had 131 representatives and 13 tumors (9.9%) (see Table 20.2.2), suggesting that overall prevalence of neoplasia in this order may be relatively high compared to other orders in the study. Six of the owls were burrowing owls (Athene cunicularia), suggesting that these birds may have a higher than average prevalence of neoplasia. Three hepatocellular neoplasms were noted in this order, all in burrowing owls. Myelolipoma, an unusual neoplasm in birds, appears to be over-represented in owls, occurring in three cases in the study. All were intracoelomic neoplasms that were extensively invasive and of undetermined origin. Interestingly, the two affected snowy owls (Nyctea scandiaca) were pen mates for most of their lives and died from these tumors within months of each other. All three of the owls with myelolipomas were from the same zoo.

SPHENISCIFORMES

Order Sphenisciformes (penguins) had 204 representatives and 11 tumors (5.4%) (see Table 20.2.2), about average compared to submissions from other avian orders. Over half of the tumor submissions (6, 55%) were squamous cell carcinomas, occurring in four different species of penguins. These data suggest that, in general, penguins may be predisposed to development of this form of neoplasm.

CICONIIFORMES

Order Ciconiiformes (herons, storks, ibises, spoonbills, New World vultures) (see Table 20.2.2) had 307 representatives and 11 tumors (3.6%), indicating the overall incidence of neoplasia in this order was slightly below the submitted average. Eight of the tumor submissions were in roseate spoonbills (Ajaia ajaja) and seven of the tumors in this species were focal or multicentric renal adenomas, a tumor that was otherwise uncommonly encountered in avian submissions. These data indicate that roseate spoonbills may be predisposed to developing this form of neoplasia. Although benign, four of these tumors contributed directly to the cause of death.

MISCELLANEOUS ORDERS

Several orders had no apparent trends in neoplastic disease. These include Columbiformes (pigeons, doves), Gruiformes (cranes, related species), Falconiformes (eagles, hawks, falcons, Old World vultures), Charadriiformes (shorebirds), Coraciiformes (kingfishers, mot mots, hornbills), Cuculiformes (turacos, cuckoos), Piciformes (woodpeckers, toucans, barbets), Struthioniformes (ratites), Coliiformes (mousebirds) and Pelecaniformes (pelicans, cormorants). Two birds of undetermined species also had neoplastic processes. Four orders, Gaviiformes (grebes, loons), Procellariiformes (fulmars), Caprimulgiformes (tawny frogmouths) and Apodiformes (hummingbirds) were represented in low numbers and had no neoplastic processes (see Table 20.2.2).

Preventive Medicine

and Screening

DAVID N. PHALEN, DVM, PhD, Dipl ABVP-Avian

We are all children at heart. When we want something, we want it now and are willing to trust in fate if it means that we can get it now. Many bird owners are like this. They want a bird, so they buy it. They don't necessarily spend the time to research the source of the bird, and often there is little money left over to make sure that their purchase is healthy. Many people buy birds and know very little about them, trusting in the information provided by their friends, the Internet or the pet store. As a result, husbandry-related diseases and infectious disease still remain a critical problem for bird owners and veterinarians.

Preventing the Introduction of Transmissible Diseases

EDUCATION

Preventive medicine is an essential element of avian medicine, aviculture and pet bird ownership. Preventive medicine begins with education. New bird owners should be provided with a basic understanding of nutrition, safe and adequate caging, household hazards, hygiene and bird behavior. Improper nutrition, poor caging, improper sanitation and improper or inadequate socialization can all lead to disease — physical and psychological — that can shorten the bird's life or result in significant lessening of its quality. Similarly, bird owners and potential bird owners must be educated to the risk factors that lead to the introduction of an infectious disease or the acquisition of a bird that is already sick.

The process of educating bird owners and potential bird owners about bird health-related issues works best when it is started before the bird is purchased. It begins at the grass roots level. Aviculturists, pet store owners and their employees have to educate themselves, assure that their stock is healthy and provide accurate information to their clients. Selling a healthy bird and providing the information to keep it healthy will result in a satisfied client and repeat business. Veterinarians also must be proactive. This means educating themselves, other veterinarians, clients and potential clients alike. Speaking to local bird clubs, contributing to newsletters and bird magazines, and being active in local and national avian veterinary organizations are all part of preventive medicine.

ACQUIRING BIRDS

The risk of disease drops dramatically if the person buying a bird researches potential sources of birds prior to purchase. It is reasonable for the buyer to ask a source for references and to request to see the facilities where the bird was raised. Aviculturists who are members of national organizations that promote bird breeding and education of their membership, such as the American Federation of Aviculture, are more likely to have a good preventive medicine plan in place. In the USA, aviculturists can become certified as having the basic elements of a preventive medicine program through the Model Avicultural Program. This or similar certification is a good indication that the aviculturalist is making efforts to produce healthy birds. It also is a positive sign when aviculturists or pet stores have an established relationship with an avian veterinarian. A great contribution to the health of avicultural birds in the USA was the cessation of indiscriminate importation of wild-caught birds. In other countries where the practice of wild bird importation persists, contagious diseases still flourish.

COMBINING DIFFERENT SPECIES OF BIRDS

Risk of disease transmission is increased when birds that originate from different parts of the world are combined. Aviculturists are strongly encouraged to focus on one group of closely related birds rather than raising a wide variety of unrelated species. If many species of birds are to be raised, separating them into different facilities by genus or at least continent of origin may reduce disease problems.

COMPONENTS OF THE PHYSICAL FACILITY 30

Any multiple bird facility, including pet stores, should have specifically designated areas including a quarantine area for newly acquired birds, a separate hospital area

for sick birds, the main facility for the breeding birds or pets, a kitchen, and if birds are being hand-raised, a nursery. A clean-up area separate from the kitchen is preferred. Obviously, pet bird owners and small hobbyists may only occasionally need a designated quarantine area, hospital or nursery, whereas large breeding operations may need these facilities all the time. Likewise, the actual physical structure of each component of the aviary will vary enormously. In the home, a bathroom or extra bedroom may serve as a hospital or quarantine area. Large breeding facilities, on the other hand, might have separate buildings for some of these components.

Other elements of aviary design can facilitate or reduce the chances of disease transmission. Outdoor aviaries are practical only in the warmer parts of the country, but they have a number of important advantages. Rain and wind naturally dilute pathogens, and freezing and direct sunlight also can inactivate some pathogens (Chapter 37, Management of Racing Pigeons). On the other hand, birds in outdoor aviaries are more likely to be attacked by raccoons and be exposed to sarcocystis from opossums. Parasites and mosquito-borne diseases also are a risk with outdoor aviaries. The chances of disease transmission can be reduced in indoor collections by making sure there is adequate ventilation and maximal separation of cages. If stocking density is high, especially if cages are stacked on top of each other, then the chances of disease transmission increase dramatically. Pacheco's disease and proventricular dilatation disease (PDD) are examples of diseases that are more likely to occur in an indoor aviary. Aspergillosis is a disease that is more likely to occur in climates with high humidity or indoor collections with poor ventilation.

Movement between these areas should be from the cleanest place to the dirtiest. The kitchen is the cleanest area, followed by the nursery, main collection of birds, hospital and quarantine area. Keeping the traffic flow through the facility to the minimum reduces the risk of disease transfer. The traffic flow can be analyzed by drawing a floor plan of a facility and using a pen to trace movement through it. The more complicated the movement pattern, the more chance for disease spread. It is often the case that a clean area has to be entered several times a day. In large facilities with multiple workers, designating individuals to work in specific areas can solve this problem. When this is not possible, changing clothes or washing up well between areas should be considered. Restricting access to the birds by the public and other bird owners also reduces the risk of disease transmission.

QUARANTINE

Quarantine will be effective only if the basic rules of quarantine are followed. The most important rule of quarantine is the "all in and all out" rule. One or more birds are brought into quarantine initially and no new birds are allowed into quarantine until the first birds have left. The location of the quarantine facility or area also is important. Just keeping a bird in a separate cage is not good enough. Some degree of distance between the new bird and the previously acquired birds is necessary. A separate building is ideal, but the garage, basement or bedroom also are acceptable.

The proper duration of quarantine is a shifting target that will vary to some degree with each circumstance. The longer the quarantine period, the more likely it is that a disease problem will be recognized before a bird is introduced into the flock. Thirty days is generally the minimum quarantine period recommended for birds, but 45 to 60 days is safer. Some aviculturists who are particularly concerned about PDD may quarantine birds for 6 to 12 months. For the quarantine to be meaningful, it has to apply to all birds entering the collection, even those birds that originated in that facility and are now returning.

Applying quarantine procedures to all birds leaving and returning to the aviary can be onerous, especially for those who show their birds. One solution to this problem is to select birds that will be shown that season and isolate them from the rest of the flock during the show season. At the end of the show season, they can be quarantined for a designated period of time and screened for disease, if necessary, before being reintroduced into the collection.

NEW BIRD EXAMINATIONS

Having every new bird or group of birds acquired examined and possibly screened for disease by an avian veterinarian is a critical element to a preventive medicine program. The extent of testing that might be done with a new bird will vary considerably according to the circumstances. If a bird is going into a home where it will be the only bird, then testing is done to show that the bird is healthy. If the bird is going into a multiple-bird household or aviary, testing is designed not only to make sure that the bird is healthy, but also to determine as best as is possible if it is infected with diseases that could be introduced to a collection.

Preventing Diseases by Common Environmental Pathogens

SANITATION

All environments contain organisms that can potentially

cause disease. These opportunistic organisms, however, cause disease only when they are allowed to reach high concentrations or when other husbandry practices are less than ideal. Candida albicans, Aspergillus spp., Pseudomonas spp. and members of the Enterobacteriaceae are examples of ubiquitous opportunistic pathogens. Diseases caused by these organisms can be greatly minimized with proper hygiene. Whenever possible, food containers should be located so that they are not contaminated with feces. Likewise, water sources should be designed and located to minimize contamination from feces and food dunked in the water. Uneaten perishable foods should be removed from the cage before they have a chance to spoil. Water and food bowls should be cleaned regularly and water sources such as automatic drip systems should be regularly flushed and disinfected. Cages should be designed so they are easily cleaned and fecal and other organic material buildup does not occur.

There are many misconceptions about sanitation and its importance. Many bird owners obsess about it. When considering the degree of sanitation necessary for a pet home or aviary, it should be remembered that birds do not come from a sterile environment and a sterile environment is not the goal. Many bird owners also obsess about transmitting viruses among birds. The best way to keep viruses out is to follow the above guidelines for preventing the introduction of these diseases. If a collection is not infected with viral disease(s), there is no potential for viral transmission within that closed collection.

Much time has been spent discussing which disinfectant is best. This focus on disinfectants ignores the most important part of sanitation, basic cleaning. Organic material must be removed first before any disinfectant can be effective. It is in the organic material that the bacteria can grow, parasite eggs are protected and viruses are at their highest concentration. In aviaries where transmissible diseases are not a problem, cleaning is usually all that is necessary. Studies have shown that one of the best ways to sanitize food and water bowls is to run them through the dishwasher. Syringes and other hand-feeding tools also are readily cleaned and for all practical purposes disinfected in the dishwasher. The dishwasher should be separate from the home kitchen dishwasher. If disinfectants are to be used, they should be used after a surface is cleaned. They work best if they are left in contact with the surface for as long as possible. It is difficult or impossible to disinfect organic material, therefore, it is impossible to disinfect dirt floors and very difficult to disinfect wood surfaces. Disinfectants may be toxic, however, if viral diseases are or have been a problem in an aviary, disinfecting food and water containers and environmental surfaces is indicated. Phenolic disinfectants and bleach are effective against most viruses and are the only disinfectants that work against viruses that do not have an envelope. Quaternary ammonium and chlorhexidine-based disinfectants are effective only against enveloped viruses.

Testing

Examination and testing of birds has two goals. The first is to make sure the newly acquired bird is healthy and does not have an infectious or non-infectious disease. The second is to make sure the bird is not subclinically infected with a disease that could be transmitted to other birds in the owner's aviary. There are two different types of testing. The first types are non-specific tests that provide general information that suggests a bird is healthy or ill, but do not specifically identify the etiology. The second types of tests are very specific and permit the identification of specific infectious agents. Because we cannot test for all infectious agents, it is common to use both types of tests when evaluating a new bird.

NON-SPECIFIC ASSAYS

The most important diagnostic assays in the broadest manner of speaking are the history, examination of the bird in the cage and the physical exam (see Chapter 6, Maximizing Information from the Physical Examination). However, it is the information derived from this phase of the workup that will lead to the development of a testing plan, and will be important in the interpretation of the results of any diagnostics that may be done.

Common non-specific diagnostic assays that are often included in the new bird exam include the complete blood cell count (CBC), chemistry panel, fecal wet mount and float, and oral and cloacal Gram stains and culture. Plasma electrophoresis and even radiographs are included as part of the new bird exam by some veterinarians. Interpretation of these diagnostic assays is discussed in detail in other chapters and only a few comments will be made about these here.

It has been the experience of the author that the CBC is a very useful tool for screening the new bird. It rarely gives a definitive diagnosis, but if abnormalities in the CBC are found it is a strong indication of an underlying health problem. The plasma electrophoresis also has considerable value, as alterations in this assay are found early in the course of infectious diseases, often before the disease becomes patent.6 Fecal wet mounts can reveal Giardia spp. infections and are the best way to detect infections with Macrorhabdus ornithogaster (megabacterium).17

The Gram stain and fecal cultures are commonly used

screening tools that have a tremendous potential for abuse. It is generally assumed that parrots should have relatively few bacteria in swabs of their oral cavity and cloaca, and that the predominate bacteria present on these surfaces should be gram-positive rods and cocci. The presence of large numbers of gram-negative bacterial rods, clostridial spores or budding yeasts is considered to be abnormal. It has been the tendency of avian veterinarians to treat birds that have predominately gram-negative flora of these areas. Likewise, when Pseudomonas spp. or members of the Enterobacteriaceae such as E. coli are cultured, it has been common practice to treat these birds.

Over time, however, it has become clear that this is not the correct approach. The gastrointestinal flora is influenced by many factors. If the bird is not outwardly ill, the presence of the so-called "pathogenic bacteria" is more often a reflection of poor nutrition or other management problems than anything else and does not mean that these organisms are causing this particular bird a problem. In these instances, improving nutrition, hygiene or other management practices will result in the Gram stain becoming normal again without treatment (see Chapter 4, Nutritional Considerations).

The use of aerobic culturing to screen birds also can lead to false impressions. Many of the normal flora found in the bird's gut are anaerobes. When cultures are performed of cloacal swabs and feces, they are generally sent in for aerobic culture. Under these circumstances, only the facultative anerobes and the aerobic bacteria grow, and the culture becomes skewed toward the smaller numbers of Pseudomonas spp. and Enterobacteriaceae that may be present.

The fecal Gram stain should be evaluated in light of the other findings in the individual bird. If the Gram stain is abnormal but the bird is otherwise healthy, management problems may be the underlying cause of the abnormal GI flora. Appropriate corrections to diet and husbandry can then be initiated. After these changes have been implemented for an adequate period (several weeks is commonly employed), a fecal Gram stain should be reexamined. If the bird has diarrhea or is showing other signs of illness and the Gram stain is abnormal, a culture may be indicated. Pending culture results, treatment with appropriate antibiotic, anti-yeast or antifungal therapy should be initiated.

Salmonellosis is a problem that is rarely seen in parrots but is common in other species of birds. Currently, many facilities require that birds be screened for infection with Salmonella spp. prior to entry. It is fairly common for otherwise normal birds to have positive fecal cultures. This poses a significant problem, as these birds

Table 21.1 | Diagnostic Assays for Psittacosis+

Assay	Sample	Effective in These Species of Birds	Day Positive after Infection	Specifics
Serology*				
Elementary body agglutination	Serum or plasma	Parrots	Approx. 14 days	Negative with successful treatment
Complement fixation	Serum or plasma	All species of birds	Approx. 21 days	May remain positive with successful treatment
Solid phase ELISA	Serum or plasma	Parrots, others?	Unknown	Not available in the USA
PCR*	Whole blood and combined oral and cloacal swab	All species of birds	Oral 5 days, blood 10 days, cloaca 15 days	Rapidly negative after the onset of treatment

⁺ Commonly affected species include pigeons, doves and parrots (particularly budgerigars & cockatiels).

cannot be shipped and it is not known if they actually are a health risk to other animals. Little work has been done to determine the success of eliminating intestinal salmonellosis with antimicrobial treatment in exotic birds; it is known that this approach does not work in poultry. Serotyping *Salmonella* isolates may be of some benefit, as certain serotypes are more commonly associated with disease in birds than others. Serology has been an extremely useful tool for the eradication of *S. pullo-rum* in poultry. Serologic screening for salmonellosis in other species has potential value.¹¹

SPECIFIC ASSAYS

In this day and age, we rely on two important types of diagnostic assays, serologic and polymerase chain reaction (PCR) assays. Serologic assays detect antibodies to specific organisms. PCR assays detect the DNA or RNA of targeted organisms. Serologic assays have the advantage of being generally inexpensive and able to be performed on an easily acquired sample (serum or plasma) that is inexpensively shipped to the laboratory. The disadvantages of serology are that these assays may not become positive until 2 to 3 weeks after infection and may remain positive after the infectious agent is no longer present. Other complicating factors related to serologic assays include non-specific substances in serum that can sometimes cause a virus-neutralizing assay to read positive at high concentrations of serum or plasma, and anticomplementary substances that can invalidate the complement fixation assay. Virus neutralization assays have the disadvantage of requiring that growing cells are always available, and these assays typically take 3 to 5 days to run. Because of the time it takes to set up these assays, they are generally performed only once a week. There are several serological assays that use a secondary antibody that is said to detect all avian immunoglobulins. This type of cross-reactivity is extremely unlikely and this type of assay cannot be recommended.14

PCR-based assays have the advantages of being extremely sensitive, able to detect pathogens in the early stages of infection, and do not require viable microorganisms to document their presence in the sample. The sensitivity of these assays also is one of their limitations. Contamination

at the sampling site or in the laboratory can give false-positive results. Obtaining a sample that contains the organism and getting it to the laboratory before it degrades also can be a problem for some PCR-based assays. Likewise, inhibitory substances such as antibiotics and the contents of droppings can cause false-negative results.

Not all PCR assays are created equal. Different laboratories offer tests with differing levels of sensitivity. It is important to use a laboratory that has a long history of experience with avian samples.

There are limitations to the sensitivity and specificity of individual infectious agent testing. The practitioner must remember that assays exist for only a select number of the potentially pathologic avian agents. Testing only for specific agents may not yield a diagnosis for an individual sick bird, nor is this testing sufficient to declare an individual bird or a collection free of disease.

PSITTACOSIS

Infection with *Chlamydophila psittaci* is common in pet birds. Clinical signs vary from none to a mild respiratory disease to a severe multisystemic, often fatal, disease. Psittacosis is particularly important in avian medicine because it can spread widely before it is recognized and because it is a zoonotic and reportable disease. Clinical signs and traditional diagnostic assays such as hematology, clinical pathology and radiology, while helpful, are generally insufficient to specifically diagnose this disease.

Serology

The elementary body agglutination assay (EBA) is a tried-and-true serologic assay that has been used for the past 10 years. It detects anti-*Chlamydophila* IgM. It can detect infected birds within 15 days of infection and generally is positive by the time a bird is showing signs of illness (Table 21.1). Another advantage of this assay is that it becomes negative with successful treatment. It has a few minor limitations. Rarely, a bird may develop signs of disease before the agglutinating antibodies are produced. Also, rarely, a bird with chronic psittacosis may be EBA negative. The EBA works very well for psittacine birds, but may not work in all species, particularly doves

^{*}A combination of the elementary body agglutination assay and PCR or the complement fixation assay and PCR is more sensitive than either test alone.

and pigeons. For doves and pigeons, the complement fixation assay (CF) is currently recommended. 10,20

The CF test detects anti-Chlamydophila IgG that is present in blood a few days to a week after anti-Chlamydophila IgM. Therefore, there is a slight delay between when the EBA and the CF become positive. The CF also may stay positive for an extended period of time after a bird has been successfully treated. To the best of the author's knowledge at this time, only one laboratory offers the CF and EBA‡. The CF is a cumbersome test and is not routinely run, so there may be a delay in getting results.

A solid phase enzyme-linked immunoassay (ELISA)^a is currently available, although not in the USA. This assay was found to compare favorably to the CF if the serum sample produced a spot as dark or darker than the positive control (J. Grimes, personal communication, 1995). Other serologic assays are offered, but have not been validated by peer-reviewed research.

PCR

PCR testing for psittacosis is another excellent way to identify infected birds. The organism can be detected in swabs of the oral cavity as early as 5 days after infection, in cloacal swabs by 10 days after infection and in the blood by 15 days after infection. The major disadvantage of the PCR is that birds that have been started on treatment before testing may be negative, and cloacal swabs that are heavily contaminated with feces may interfere with this assay. The sensitivity of this assay is improved if both blood and combined oral and cloacal swabs are tested.1,8

No test is 100% sensitive. Therefore, if the greatest degree of sensitivity is sought, the PCR and the EBA and egg inoculation culture or tissue culture could both be performed when screening parrots. PCR can be combined with the CF when screening doves and pigeons.

Chlamydopbila psittaci infections can occur in almost any species of caged bird. The author recommends testing for this organism in most birds presented for new bird purchase examinations. The author especially recommends testing cockatiels (Nymphicus hollandicus) as they can carry this bacterium and not demonstrate clinical signs of disease. The few cases of human infections the author has observed have been acquired from an otherwise healthy pet cockatiel. Pigeons and doves are commonly infected with C. psittaci and should be routinely tested.

MYCOBACTERIOSIS

Several mycobacterial species, including Mycobacterium avium, M. genavense, M. fortuitum and M. tuberculosis, cause mycobacteriosis in birds. Mycobacterium avium

and M. genavense cause the majority of avian infections. The time between infection and onset of clinical signs is long, possibly several months. As a result, infected but outwardly healthy birds may be introduced to a collection and infection disseminated widely before it is recognized. Mycobacteriosis is particularly common in captive populations of grey-cheeked parakeets (Brotogeris pyrrboptera), canary-winged parakeets (B. versicolorus), Pionus spp., canaries (Serinus canarius), finches, the red siskin (Carduelis cuculatta) and waterfowl. Mycobacterial infections result in a multisystemic but slowly progressive disease that can present with many possible signs. Because signs are rarely specific and infection can remain inapparent for extended periods of time, ancillary diagnostic assays are needed.33

Detection of the Organism

Many mycobacterial infections colonize the intestinal lamina propria and mycobacteria can be shed in the feces. Acid-fast stains of the feces will reveal the organisms in some cases, but this assay has a very low sensitivity and is of limited value as a screening tool. A PCR assay## is now being offered that can detect mycobacteria in the feces. The major limitation with this assay is that not all birds with avian tuberculosis are actively shedding the organism, or they shed the organism in small numbers or intermittently. A negative result with the PCR assay, therefore, does not rule out the possibility of infection. The technology associated with PCR diagnostics for avian mycobacteriosis is developing rapidly and this assay has significant long-term potential.33

Serology

Mounting evidence suggests that serology will be an important tool for detecting birds with mycobacteriosis. At the time of this writing, however, serologic assays for mycobacteriosis are still experimental. Successful serologic assays will have to be applicable to all species that are to be tested, and they will have to be able to detect infection with the multiple species of mycobacteria that infect birds. A complement fixation assay was developed to detect mycobacterial antibodies. This assay had the advantage that it did not require species-specific reagents. The complement fixation reaction, however, was very cumbersome and required reagents that had a short shelf life, making it impractical to use. Additionally, culture filtrate was used for this assay and it was necessary to run multiple tests with antigens from each specific serotype of M. avium in order to detect all of the infected birds.18

Indirect ELISAs have been used successfully to detect antimycobacterial antibodies in waterfowl and quail. The indirect ELISA, however, requires a specific secondary

antibody, limiting its usefulness to closely related species. A blocking ELISA has been developed that circumvents the need for a specific secondary antibody. This assay has been tested in canaries, white-winged wood ducks and quail with known or suspected *M. avium* infections. At this point, there has been good correlation between infected birds and birds that are positive with this assay. Protoplasmic antigen from one serotype of *M. avium* was found to cross-react with all other serotypes tested. However, early work suggests that antibodies to other species of mycobacteria can be detected only if their specific antigen is used.³⁴

The immunological response of the host also may complicate the interpretation of serologic assays for mycobacteriosis. The complement fixation assay was used to screen ring-necked turtledoves for infection. The wild-type birds in this collection were all antibody positive, but the majority of the birds that had the white color mutation were seronegative. It is not known if the failure of an antibody response in these birds is limited to this particular color mutation or also may occur in other species and color mutations of birds¹⁸ (see Chapter 28, Implications of Mycobacteria in Clinical Disorders).

MYCOPLASMOSIS

Mycoplasmosis is a common disease of pigeons and poultry, but occurs infrequently in companion birds with the possible exception of cockatiels. The disease in pigeons and companion birds is characterized by conjunctivitis and upper respiratory signs, and less frequently pneumonia. Distention of the infraorbital sinus with fluid or purulent material is common. PCR assays for *Mycoplasma* spp. have been developed and are offered by many diagnostic laboratories. Some of these assays will amplify DNA from all mycoplasmas, so that a *Mycoplasma* sp. infecting a parrot could be detected even if it was not one of the common poultry pathogens. The disadvantage of this assay is that just because mycoplasma is present in a lesion, it is not conclusive proof that it is the cause of disease.

ASPERGILLOSIS

Aspergillosis is an infection of the respiratory system that occurs sporadically in a wide range of birds (see Chapter 29, Implications of Mycoses in Clinical Disorders). Birds from cold and dry climates are highly susceptible to infection. Environments that are conducive to the environmental growth of *Aspergillus* spp. and environments that are poorly ventilated will result in an increased incidence of aspergillosis. Disease can be localized to the upper airways or the syrinx, or it may involve the air sacs and lungs. Respiratory signs are a common feature of this disease, but a bird may not manifest signs until the

disease is advanced. Radiographs, endoscopy and biopsy, cytology and hematology are all valuable tools in the diagnosis of this disease. Even with all these assays, the diagnosis of aspergillosis is often a difficult one.

The diagnosis of aspergillosis has been most extensively studied in humans. Ancillary diagnostic assays used in people include PCR to detect Aspergillus DNA from blood, an ELISA to detect Aspergillus antigen and an ELISA to detect anti-Aspergillus antibody. These studies clearly indicate that even a combination of these three assays will not be adequate to detect many cases of aspergillosis. 45 The problem comes from the fact that most people who contract aspergillosis are immunocompromised. This also may be true in birds. If the infected person's immune system is adequate to contain the disease and the organism is localized in a walled-off granuloma, then these individuals are found to produce antibody. People with generalized disease are generally severely immunocompromised and they do not produce antibody. In these people, Aspergillus antigen and DNA are most likely to be found in the blood, but they are not when the lesion is encapsulated. If the pathophysiology of avian aspergillosis resembles that seen in humans, then none of these assays are likely to detect infection in most infected birds. A combination of these assays may be more specific, but false negatives are to be expected.

Serology

Extended efforts have been undertaken to develop a serologic assay for birds infected with Aspergillus spp. This work was pioneered at The Minnesota Raptor Center, which currently offers an ELISA assay for the detection of anti-Aspergillus antibodies##. Differing secondary antibodies are used in this assay, depending on the species of bird to be tested. Using well-defined clinical case material, the assay has been validated for use in several species of Falconiformes, but as designed does not work in owls. Immune suppression appears to accompany aspergillosis in raptors. Prior to treatment, many raptors have little or no detectable antibody. Successful treatment results in a subsequent rise followed by a decline in antibody titers. A failure of antibody titers to rise with treatment or an increase in the titers without the expected decrease is considered to be a poor prognostic sign. Thus a medium to high positive antibody titer is highly suggestive of disease. However, negative to low positive results are inconclusive.24 Similar results were found in penguins with aspergillosis.25 Birds with high antibody titers, high beta and gamma globulins, and albumen concentrations above 1.8 g/dl had a favorable prognosis. In contrast, birds with low or undetectable antibody titers and albumin levels below 1.8 g/dl had a poor prognosis.

The accuracy of available serologic and antigen capture assays for the diagnosis of aspergillosis in parrots has been inadequately studied. In one study, a commercially available ELISA for anti-Aspergillus antibodies and antigen capture assay**** was evaluated in seven birds with confirmed aspergillosis. Of these birds, only one was found to be weakly positive with serology and three birds were positive, two weakly, with the antigen detection assay, suggesting that either parrots in this study did not make anti-Aspergillus antibodies and had little circulating antigen, or that these assays were not sensitive.13 A second study of ten birds found a higher percentage of sero- and antigen-positive birds; however, in neither study were non-infected birds tested, so the specificity of these assays remains to be determined.16 Currently, the author does not recommend using any of the available Aspergillus assays for routine screening of parrots.

PSITTACINE BEAK AND FEATHER DISEASE VIRUS (PBFDV)

PBFDV is a common infection of wild birds in Australia. In the USA and possibly elsewhere, this virus is enzootic in many lovebird collections and also is seen to a lesser degree in budgerigar aviaries. Disease is seen in many species of parrots, including African grey parrots, lovebirds, budgerigars, lories, lorikeets, eclectus parrots and cockatoos. Infection also occurs in Neotropical parrots, but disease is rare and infections are transient in most cases.

The sequence of the PBFDVs genome varies up to 16% between isolates. This has diagnostic significance, as PCR primers have to be designed in the conserved region of this virus (ORF1) if they are to detect all variants of this virus.^{3,37} Recently, a specific variant of PBFDV has been recognized in collections of lories in the USA. It also is reported to occur in lovebirds.²⁶ Its sequence and its relationship to previously published sequences of the PBFDV have not been reported. PCR primers derived from the ORF1 also can detect this variant. Primers also have been designed to differentiate it from other PBFDVs. Lories with this infection may remain viremic for 6 months or more without showing clinical signs. Lories that develop clinical signs often die, but some will recover.31

Serology

Birds that become infected with PBFDV but do not develop disease have high antibody titers. Birds that do develop disease have low antibody titers or no antibody at all. A hemagglutination assay has been developed to detect serum antibodies to PBFDV. Serum antibody has been detected within 1 to 2 weeks of exposure. This assay has been effectively used to study the prevalence of PBFDV infections in wild Australian parrots. Because

PBFDV agglutinates only red blood cells from a few species of cockatoos, this assay is not practical outside of Australia.23

PCR

Birds become viremic 7 to 14 days after infection with PBFDV. If the birds are unable to mount an appropriate immune response they will remain viremic. If they do mount an appropriate immune response they cease to be viremic. Virus, however, may persist in the feathers and possibly the skin, so that these birds are a potential source of infection until their next molt. PCR is done on heparinized blood.7 If multiple birds are to be sampled, care must be taken to prevent contamination between samples. In most circumstances, birds that are PCR positive and have clinical signs of disease will remain positive and are likely to die from their infection. Birds that are positive but are not showing signs of disease should be retested in 3 months. If they are negative at that time they are thought to be cured. Rarely, lories, lovebirds and occasionally other species of parrots will develop clinical disease, but will then recover and become virus negative.

It has been suggested that it is important to differentiate between the lory variant of PBFDV and the other variants. The author does not agree with this conclusion. Although the lory variant may behave somewhat differently than other PBFDV variants, it is still pathogenic, so the significance of a positive test is the same in a lory or any other parrot species, regardless of the variant.31

PBFDV infection in lovebirds (Agapornis spp.) may not follow the same patterns as seen in other parrots. PBFDV is widespread in commercial lovebird collections, but disease is rare. It is the author's impression that virus shedding may persist more than 3 months in birds that never show signs of disease.26

AVIAN POLYOMAVIRUS (APV)

APV is a common infection of a wide range of parrots. APV causes morbidity and mortality in nestling budgerigars (Melopsittacus undulatus), Indian ring-necked parakeets (Psittacula krameri), lovebirds and many parrots. Disease is less common in nestlings of other Old World parrots. Nestling budgerigars in aviaries with enzootic APV become viremic within 7 days of hatch and are serologically positive by 10 days after hatch. If they survive infection, fecal shedding may persist for 6 months or longer, but ceases at some point after the birds become sexually mature. Although they stop shedding virus, infected budgerigars will remain seropositive for life. 15,16 Nestling parrots of other species become viremic within 2 weeks of infection. They also develop virus-neutralizing antibody at

approximately 14 days postinfection. Antibody titers in most species of nestlings that survive infection are maintained for 10 or more years and possibly for life. Viremia persists for 6 to 8 weeks in most cases. Fecal shedding begins shortly after the onset of viremia, but persists for as long as 12 to 16 weeks. ²¹ In rare cases, viremia and fecal virus shedding may persist for more than 10 months. ⁷ The duration of viremia and virus shedding in adult birds infected with APV has been studied in only a limited number of birds. However, it appears that viremia and virus shedding occurs only briefly in mature birds or not at all. ²¹ Viremia and virus shedding also are significantly impacted by concurrent infections with PBFDV. Birds with co-infections appear to shed APV continuously and may never clear the virus. ¹⁶

Serology

An excellent virus-neutralizing (VN) assay has been developed to detect antibodies that neutralize APV. In this assay, virus is first incubated with two-fold dilutions of serum or heparinized plasma. The virus-plasma mixtures are then incubated with chicken embryo fibro-blasts, the fibroblasts are washed and the cells are monitored for cytopathic effects (CPE). If CPE do occur at the *bighest* concentration of serum, then the bird did not have neutralizing antibody. If virus growth is inhibited and CPE do not occur, then the bird did have neutralizing antibody. In the author's hands, this assay takes 5 days to complete.¹⁵

Use of the APV VN

Parrots infected with APV may begin shedding virus prior to seroconversion and maintain high antibody titers many years after they stop shedding virus. Therefore, the serologic status of a bird is not a good indicator of virus shedding. Sensitive PCR assays should be used in place of serology to detect virus-shedding birds. The APV VN has some limited value in epidemiologic studies and could be used to determine if APV had ever been in a collection. Under these circumstances the immunization status of the birds should be considered. Nestlings do not produce virus-neutralizing antibody to the commercial APV vaccine. Therefore, antibody-positive nestlings have been infected with APV. Adult parrots do develop neutralizing antibody following immunization, but their antibody titers are typically low compared to those seen in birds that survived infection.19

Use of the APV PCR

Viremia may precede virus shedding and virus shedding continues after the cessation of viremia; therefore, combined oral and cloacal swabs and heparinized blood should be submitted for PCR analysis. If blood is tested alone, many virus-shedding birds will be missed. It

appears that all species of parrots have the potential to become infected with and shed APV, so all birds that are going into an aviary where they might expose nestlings should be tested. Nestlings that survive an outbreak of APV are assumed to be shedding virus. Therefore, testing birds 4 months after the outbreak when virus shedding should have stopped, rather than immediately after the outbreak when virus shedding is expected, best uses the owner's resources.²¹

Testing birds older than 16 weeks that are going into a single-bird household is of questionable value. If they test positive and are not sick, they will shed transiently and stop shedding. If a bird is positive at 16 weeks, it has already been infected and will not generally become clinically ill. It will continue to shed for some time and it should be isolated from other birds.

The author seriously doubts that the veterinarian will be able to detect an infected bird that will subsequently come down with disease as, in his experience, the onset of viremia and the onset of disease occur very close together.

When the value of testing blood was first recognized, it was suggested that PCR of blood detected only fragments of DNA and that a positive did not reflect the true infection status of the bird. It also was suggested that immunized birds that were blood PCR positive were positive because of DNA present in the vaccine. Both these assumptions have been proven to be false. Therefore, if a bird is positive by blood PCR, it is infected with APV.¹⁹ If they test positive and do not have APV disease, they will shed transiently and then stop shedding.

PSITTACID HERPESVIRUSES (PsHVs) OR PACHECO'S DISEASE VIRUSES

PsHVs are the causative agent of Pacheco's disease. Pacheco's disease occurs in sporadic outbreaks in newly formed and long-established parrot collections. Losses can range from a single bird up to hundreds of birds. Generally, birds that develop clinical Pacheco's disease die. There are four major genotypes of PsHVs. All are capable of causing Pacheco's disease and genotypes 1, 2 and 3 are capable of causing internal papillomas. 32,35,36 Outbreaks of Pacheco's disease occur when carrier birds expose naïve birds. The dynamics of each outbreak will depend on the genotype of the virus and the species of birds involved. In some collections, Pacheco's disease will not occur, but over time multiple birds will develop papillomas.

Macaws, Amazon parrots and some species of conures are most likely to be carriers of PsHVs. Infection prevalence appears to be higher in imported wild-caught birds. Infection also has been recognized in cockatoos and African grey parrots, and under some circumstances it also may occur in lovebirds and cockatiels. The list of potential carrier species likely will grow as more is learned about these viruses. Any bird that survives an outbreak of Pacheco's disease should be considered infected until shown otherwise. Mounting evidence suggests that parent-to-offspring transmission occurs. The offspring may remain asymptomatic or develop internal papillomatosis, depending on the genotype of the virus. It appears that once a bird is infected they will be infected for life. This includes survivors of Pacheco's disease that were treated with acyclovir.

The key to preventing Pacheco's outbreaks and internal papillomatosis is keeping carrier birds out of the collection or, if they are already in the collection, isolating them from birds that are not infected. Studies to date show that PsHVs in carrier birds are present in significant concentrations in the mucous membranes of the cloaca and oral mucosa. Swabs of these surfaces can be tested by PCR. Virus also may be detected in blood, but concentrations of virus are low in the blood and in one study blood PCR was inconsistently positive, while mucosal swabs were more dependably positive. In rare individuals, birds have been identified that are only blood positive. The biological significance of this is not known; until it is, it is recommended that both blood and combined oral and cloacal swabs be used for PsHV PCR.²²

PCR

Recently discovered sequence data has permitted the development of a single PCR assay that can detect all four genotypes of the PsHV (R. Dahlhausen, personal communication, 2003). Preliminary work with less ideal primer sets suggests that PCR of blood and a combined oral and cloacal swab will detect the majority of birds unapparently infected with PsHVs.

Serology

There are three major serogroups of the PsHV⁹ Serotype 1 contains genotypes 1 and 4, serotype 2 contains genotype 2 and serotype 3 contains genotype 3.³⁶ It is clear that many birds that are infected with PsHVs are seropositive. It still remains to be determined, however, if all birds infected with PsHVs will demonstrate positive serologic results. Preliminary evidence suggests that antibodies to one serotype inconsistently neutralize viruses of other serotypes.²² Therefore, if serology is to be used to detect PsHV-infected birds, multiple assays using all three viruses or their antigens will have to be run.

PARAMYXOVIRUS 3 (PMV-3)

PMV-3 is a common cause of disease in the Australian grass parakeets (*Neophema* spp.). Clinical signs are vari-

able and include central nervous system disease, respiratory signs, diarrhea and signs of pancreatic insufficiency. 28,29 In a recent report of an outbreak of PMV-3 in a pet store, the hemagglutination inhibition assay (HI) was found to be a sensitive means of detecting infected birds.14 Others have tried serologic methods for detecting subclinical infections of PMV-3 in Neophema and other species with little success. 12,29 This discrepancy may be due to the duration of the infection at the time serology is performed. In a recent study with PMV-1, low levels of antibody were detected in African grey parrots. These antibodies were detectable with an experimental ELISA, but not with the HI. This assay is currently under development and may prove useful in the future.14 In disease outbreaks where PMV-3 is suspected, submission of proper samples for histopathology is currently the most accurate method of confirmation.

Applied Preventive Medicine

TESTING NEWLY ACQUIRED BIRDS

The ultimate decision as to what type of testing should be done for a particular bird will depend on the specific details regarding the source of the bird, species of the bird, the aviary or home into which it is going, the resources of the owner and findings on physical examination. Non-specific assays such as CBC, oral and fecal Gram stain, protein electrophoresis, fecal wet mount and fecal floatation can be applied to all birds. (Ed. Note: In some practitioners' experience, a negative fecal flotation has not correlated with the absence of intestinal parasites). Ascarids are commonly expelled from birds, especially those with previous exposure to warm, outdoor environments, following the administration of an appropriate anthelmintic. This occurs in birds with negative fecal flotations, and routine deworming may be advised in these situations (M. Wissman, personal communication, 2002).

Fecal and oral cultures are indicated if abnormalities are found on the Gram stains and birds show other evidence of illness. Chemistry panels are most likely to identify problems in older or unthrifty birds, but can be useful in detecting early disease or establishing baselines for future reference, even in clinically healthy individuals. Radiographs are relatively costly tests that can be used for screening. Generally, however, they are used only when there is some other indication of disease. Currently, the choice of serologic and PCR-based testing is best tailored to the species and background of the bird being examined (Table 21.2 and Table 21.1).

Table 21.2 | Diagnostic Tests Used to Screen for Specific Infectious Diseases

Infectious Agent	Assay	Sample for Testing	Species Commonly Infected	Sensitivity	Specificity
Mycobacteria	PCR	Feces	Brotogeris spp., canaries, finches,	Fair	Good
	Serology	Serum or plasma	red siskins, waterfowl	Experimental	Experimental
M. ornithogaster	Wet mount	Feces	Budgerigars, finches, cockatiels, parrotlets, lovebirds, lories, other	Fair to poor	Good if many organ- isms present
PBFDV	PCR	Blood*	Old World parrots	Excellent	Excellent
APV	PCR	Blood and swabs**	Lovebirds, budgerigars, all parrots	Excellent	Excellent
	Serology	Serum or plasma	recently exposed to other birds	Proof of previous or current infection	Does not reflect virus- shedding status
PsHV	PCR	Blood and swabs	Macaws, Amazon parrots, conures,	Excellent	Excellent
	Serology	Serum or plasma	others?	Unknown	Unknown
PMV-3	HI+	Serum or plasma	Neophema spp., others?	Questionable in chronic infection	Good
	ELISA++	Serum or plasma		Experimental	Experimental

^{*}Heparinized blood

++ ELISA: Enzyme-linked immunoassay

There is a saying: "Be careful for what you look for, because you may find it." This is particularly applicable to testing new birds. It is incumbent upon practitioners to know everything that they can about the tests they are using so that if one does come back positive, it can be properly interpreted. It also is important to correlate test results with the entire clinical picture. If the testing results don't make sense, then repeat those assays or have them performed by a different laboratory.

PREVENTIVE MEDICINE AND THE VETERINARY HOSPITAL

It is a common practice for veterinarians to board birds. There is no doubt that this is a valuable service to the veterinarian's clients, but it also poses challenges for the prevention of disease transmission. The greatest risk occurs if birds of uncertain infection status are housed in the same room. If all birds are screened for PBFDV, APV, PsHVs and *Chlamydophila psittaci* before they are allowed to board, then the risk of disease is diminished. There is no test for birds that have the etiologic agent of proventricular dilatation disease, however, so the transmission of this disease cannot be prevented. Other strategies for preventing disease transmission would be to keep birds in isolettes or to house birds separately in different parts of the hospital.

Veterinarians see sick birds and therefore will have birds with infectious diseases in their hospital. A protocol should be developed for every hospital for routine cleaning of the exam, treatment and hospital rooms and caging. Routine PCR testing of swabs of these environments can be used to determine if the cleaning is effective. Boarding birds should be housed separately from hospitalized birds.

PREVENTIVE MEDICINE AND BIRD MARTS

A common way for aviculturists to sell their birds is to bring them to bird marts or bird fairs that are sponsored

by local bird clubs. These marts serve many valuable purposes. They provide an important outlet for the sale of birds and at the same time raise money for the sponsoring organizations. This money is used to help support the bird club and in many cases to fund research and conservation efforts. The bringing together of birds from multiple premises into a confined area and the handling of these birds by the general public, however, results in the ideal opportunity for disease spread, the most common of which is APV.

There are preventive measures that can be taken that will help to mitigate disease transmission at bird marts. The most important is to limit sale of birds to those that are completely weaned. Weaned birds will rarely, if ever, develop APV disease although they are still susceptible to infection. Birds that are taken to a bird mart but not sold should be quarantined away from the rest of the breeder's birds until they can be sold. A policy of not letting anyone handle birds unless they have bought them also will reduce the spread of disease. Finally, cages made of clear, hard plastic panels can be used to display birds that are for sale. Ideally, these cages would have a fan in the back that draws air out of the cage and a Hepa filter in the front to filter out potential pathogens. Even without these fans, cages made from clear plastic panels are much better than wire cages. If nestlings are allowed at bird marts, then they should be confined to brooders or cages made from this material and taken out to the car or hotel room for feeding. Nestlings that are not sold must go into quarantine after the show.

PREVENTIVE MEDICINE IN THE PET STORE

Pet store owners and managers who intend to sell birds first need to consider what market it is that they wish to reach. Budgerigars, cockatiels, lovebirds, canaries and finches appeal to one type of customer and come with their own significant disease problems. The larger species

⁺ HI: Hemoagglutination inhibition

^{**}Combined oral and cloacal swab

of birds appeal to other types of customers. Combining these birds can lead to additional health problems.

It has been a common practice in the USA for individual producers of cockatiels, lovebirds, budgerigars and finches to sell their birds to buyers who combine birds from multiple sources and ship them to other sellers who distribute them to pet stores. This practice maximizes the potential for disease transmission. Cockatiels supplied in this manner have a high incidence of psittacosis. Similarly, lovebirds and budgerigars from these sources are commonly infected with APV, and lovebirds are commonly infected with the PBFDV. When infected birds are mixed with birds from clean collections, disease transmission is likely. When these birds come into a pet store, not only may they be unhealthy, but they also are an important source of infection for other parrots whose retail value may be much higher. The classic example of this is APV outbreaks that occur in nestling macaws, conures and eclectus parrots 2 weeks after they are brought into a pet store. The tendency in these circumstances is to blame the breeder who supplied the nestlings that died, but the problem lies with the budgerigars and lovebirds in the store that are actively shedding virus and that fatally exposed these birds after they entered the store.

It has been the author's experience that pet stores have healthier stock if they establish a relationship with one or more local breeders and buy birds directly from them. If the local breeder can see the possibility of a sustained market, they are more willing to spend money to verify that their flock does not contain the common diseases that can cause so many problems in the pet store. Aviaries that supply birds to stores can be screened for infectious diseases by environmental testing or testing a random selection of birds. The specific types of screening tests should be tailored to the type of birds being purchased, and this protocol is best done with the assistance of an avian veterinarian. Subsequently, if appropriate biosecurity measures are maintained, the pet store owners can feel assured that they are buying clean stock. This requires some initial investment, but this investment is spread out over many birds and is well worth it.

Other management techniques can be used to minimize the risk of disease. First and foremost, a relationship should be established with an avian veterinarian. The veterinarian's role is to provide advice that will help minimize the risk of disease, but at the same time will not result in huge expenditures. A general rule is that any change should increase the pet store owner's profit. If it does not, then another approach should be taken.

The two diseases that can substantially impact the pet store are APV and psittacosis. APV is predominately a dis-

ease of nestling parrots. Lovebirds and budgerigars from many sources may shed this virus. The risk of APV disease can be greatly reduced if stores buy only weaned birds. Alternately, some stores may choose not to sell the smaller species of birds. If nestlings are to be present in the store, all the sources of all birds brought into the store need to be screened for APV. Setting up a separate bird room that the public can look into but may enter only with supervision will help to keep customers from bringing disease into the store. If a customer wants to see a bird, they may be required to put on a clean smock and gloves and possibly even dip their feet in a foot bath before entry into the bird room. If economics require that nestlings that are still being hand-fed be purchased, an alternate approach to keeping them healthy is to raise and wean them in isolation away from the store.

Psittacosis is very common in cockatiels and can occur in any species of parrot. It can cause widespread disease in pet store birds, requires a long treatment period, is a reportable disease in most areas and is transmissible to people. All sources of birds should be tested for this disease.

Quarantine is another element of the preventive medicine that can provide important dividends to the pet store. All birds coming into the store should be isolated for some period of time before they are mixed with other birds in the store. If the incoming birds have been exposed to disease, it is likely that they will begin showing signs during the quarantine period. It has been common practice for some distributors to treat some species of birds with tetracyclines for variable lengths of time before they are sold. This can mask signs of psittacosis but may not cure the birds. Once the birds are off medication signs will often reappear. Money is a factor in any preventive health plan and a careful balance must be established between cost of preventive medicine and its benefits. Careful consideration should be taken so that all preventive measures have a clear economic benefit.

Finally, if preventive measures are undertaken, the public should be made aware of what is being done and birds should be sold as value-added products. For instance, if extensive efforts are undertaken to acquire polyomavirusfree birds, then these birds should be advertised as such. When the consumer sees that one store is concerned about infectious diseases and others do not place similar emphasis on them, the consumer will buy from that store, even if the cost may be somewhat higher.

IMMUNIZATION AND PREVENTIVE MEDICINE

Immunization for poxvirus, paramyxovirus-1 and salmonella can be important elements of disease control in racing pigeons. Poxvirus immunization also is advised for canaries that are raised outdoors. The current parrot herpesvirus vaccine in the USA is a monovalent vaccine. The exact serotype present in the current vaccine is not known at the time of this writing. It is expected that this vaccine will protect against the serotype from which it is derived. It is not known, however, if this vaccine will protect against other serotypes. In collections of birds where there is a high risk of Pacheco's disease, use of this vaccine may be indicated. A polyvalent vaccine that would protect against infection with the three common serotypes may someday be developed and could potentially protect against Pacheco's disease and internal papillomatosis.

The value of the equine West Nile virus vaccine in birds remains to be proven. The author was not aware of adverse reactions to the vaccine the first year that it was used. However, a hemolytic anemia has been reported in lories that were immunized a year after the first set of immunizations. This problem, however, has not been seen in another collection of birds immunized 2 years in a row. Given that the current information about the

potential value and potential risks of the West Nile virus vaccine is minimal, it should probably be used only as a last resort. Screening in the enclosure of high-risk birds and other mosquito control programs may be the safest ways to prevent disease from the West Nile virus.

A discussion of the avian polyomavirus vaccine is included in Chapter 32, Implications of Viruses in Clinical Disorders. The author believes that management practices are critical to the control of avian polyomavirus, and that there are few circumstances where immunization would be helpful in its control.

Diagnostic Value of

Hematology

JAIME SAMOUR, MVZ, PhD, Dipl ECAMS

Hematology is the discipline of medical science that studies the blood and blood-forming tissues, and is currently considered an integral part of clinical laboratory diagnostics in avian medicine. Hematology assays seldom provide an etiological diagnosis, but they remain, nevertheless, indispensable diagnostic tools to evaluate health and disease in individuals, to monitor the progress of diseases, to evaluate the response to therapy and to offer a prognosis.

The routine collection and processing of blood samples allows the evaluation of the hematologic response to disease. In addition, the creation of hematology databases is important in establishing reference values for various avian species.

In the past 15 years, significant advances have been made in the use of hematology assays in the differential diagnosis of pathologic conditions in avian species. This appears to have developed parallel to other areas such as nutrition, wellness examinations, anesthesia, surgery and therapeutics.

The processing of hematology samples also has been enhanced in recent years. In the past, automatic analysis of avian blood samples was basically limited to total red cell counts using the cell counters^a that were available and making manual adjustments of the thresholds and current aperture settings. More recently, the analysis of avian blood samples has received a significant boost with the advent of more comprehensive and accurate automatic analytical systems based on laser flow cytometry.^b This methodology is based on the measurement of scattered laser light, which fluctuates with the size of the

Table 22.1 | Materials Needed for Blood Sample Collection

- Syringe, 1-ml or 3-ml, disposable

cell, the complexity of the cell (eg, overall shape, nucleus-to-cytoplasm ratio, granulation), and the size and shape of the nucleus after blood cells are exposed to a laser beam. The laser flow cytometry unit produces a graphic display containing a total optical white cell count, white cell differential count expressed in percentage, absolute values and total red cell count, hemoglobin measurement by the cyanmethemoglobin method, thrombocyte count, and white cell count by cell-lysing impedance measurement of cell nuclei. However, the use of laser flow cytometric technology in avian species is not free from deficiencies.

There are certain pathological conditions in which the presence of enlarged thrombocytes (commonly referred to as megathrombocytes) in the blood film appear to be a characteristic hemoresponse. For instance, in the houbara bustard (Chlamydotis undulata macqueenii), the mean thrombocyte measurements in birds undergoing chronic inflammation (severe shoulder injury as a result of repeated crashing against the enclosure wall) were 9.22 \pm 0.21 μ m length and 8.10 \pm 0.19 μ m width compared with 5.47 \pm 0.12 μ m length and 4.96 \pm 0.10 μm width in clinically normal birds. The mean diameter of lymphocytes in clinically normal houbara bustards is 7.7 μ m;⁵¹ however, there are other species, such as the kori bustard (Ardeotis kori), in which the presence of large and small thrombocytes in the same blood film appears to be normal.⁵¹ It is, therefore, probable that a sample containing megathrombocytes would yield a high lymphocyte count under an automatic analytical system, as it would be impossible for even a sophisticated unit to differentiate between lymphocytes and megathrombocytes. When dealing with such species, the software would require some adjustments in order to properly differentiate these cells. This would obviously imply the need to carry out extensive calibration based on repeated manual assessments on a significant number of samples.

Furthermore, in certain species it is relatively common to find large and small lymphocytes in the same blood film. 4,12,26,31,35 This phenomenon has been observed in many psittacine species. Clinically normal kori bustards, for instance, demonstrated a mean diameter for small lymphocytes of $7.2 \pm 0.12 \,\mu\text{m}$, whereas the mean diameter of large lymphocytes was $10.7 \pm 0.16 \,\mu\text{m}$. There-

fore, total white blood cell counts and differential white blood cell counts cannot be accepted as reliable in every clinical case and in every species if the values were estimated by laser flow cytometry. It is, therefore, highly recommended to re-evaluate these samples using manual methods. Clearly, the clinician must be fully familiar with the materials and methods of hematology analysis in order to assess and understand the results.

Blood Sample Collection

It is essential that blood samples be obtained from avian species by or under the supervision of a veterinarian who is experienced with avian venipuncture. The assistant, if one is used, also should be comfortable with restraint and handling techniques. The techniques used vary according to personal preferences and the species being handled. Materials needed for blood sample collection, ie, syringes, slides, tubes, should be labeled in advance and readily accessible (Table 22.1).

METHOD

The total blood volume in clinically normal birds is in the range of 6 to 11 ml per 100 g of body weight.⁵⁴ Thus, a bird weighing 250 g would have approximately 15 to 27.5 ml of blood, of which, in a clinically normal individual, up to 10% (1.5-2.7 ml) can be safely withdrawn without having any detrimental effect on the patient. However, 0.2 to 0.3 ml of blood is generally sufficient to carry out a comprehensive hematology examination in a bird.

In birds, blood samples are commonly collected using the right jugular vein (v. *jugularis dextra*), as this is generally larger than the left jugular vein in most avian species (Fig 22.1a). Other preferred sites include the basilic vein (Fig 22.1b) (v. *cutanea ulnaris superficialis*) and the caudal tibial vein (v. *metatarsalis plantaris superficialis*) (Fig 22.1c).

The methodology used for the collection of blood samples varies according to the species and the site selected (Fig 22.1d-h). For example, in long-legged birds such as large bustards, cranes and storks, the jugular or caudal tibial veins are very often used. In the author's opinion, blood samples should be collected from the heart or the occipital sinus only if these birds are under anesthesia and are to be euthanized. It is a poor practice to collect blood samples from clipped nails, as cell distribution and cell content is invariably affected.

The author prefers obtaining blood samples from most bird species from 200 to 4000 g using a basilic vein

Fig 22.1a | Right jugular being blocked in a love bird and a syringe with a 27 ga needle that has been bent to allow venipuncture.

Fig 22.1c | Caudal tibial vein in a love bird.

while the bird is in dorsal recumbency, although most practitioners in the US dealing with psittacine species prefer jugular venipuncture. In most avian species, the optimal area for collecting a blood sample from a basilic vein is along the medial section of the vein. The preferred side is from the right wing if the practitioner is right-handed, while the left wing is the preferred side if the practitioner is left-handed. Venipuncture immediately above the elbow joint is not recommended, as hemostasis is difficult to achieve at this site in most cases. The application of digital pressure with the thumb at the proximal humerus would help in raising the vein, making it clearly visible running parallel to the external aspect of the humerus. After separating the feathers and preparing the site with an alcohol swab, the bent needle is gently inserted into the vein at an approximately 45° angle. The sample can now be collected, taking precaution not to exert high negative pressure while withdrawing with the syringe because this will invariably result in the collapse of the vein.

While withdrawing the sample, it is recommended to continue maintaining pressure on the proximal

Fig 22.1b | The blocked basilic vein showing the torturous nature of the vein making cannulation with a hypodermic needle difficult at best

humerus to ensure a raised and well-defined vein. The method of approaching the basilic vein dorsally by entering under the adjacent tendon prevents hematoma formation because the underlying tissue exerts pressure on the venipuncture site when the needle is withdrawn. It is essential to avoid sudden movements that can alarm the bird and trigger a struggle, as this can easily lacerate the vein and result in a hematoma or, worse, a severe hemorrhage. After collection, a small ball of dry cotton should be placed over the venipuncture site and the wing closed to maintain pressure over the site for a few seconds. It is strongly advisable to check the venipuncture site before releasing the bird back to its enclosure to ensure no post-collection hemorrhage has occurred. Any sample that contains clots should be rejected, as the processing of such samples would invariably lead to imprecise and therefore misleading results.

STORAGE OF BLOOD SAMPLES

After collection, the needle should be removed and the blood gently deposited into a 0.5 to 1.0 ml commercially available pediatric blood storage tube containing the anticoagulant agent ethylenediamine tetra-acetic acid (EDTA) (1.5 mg/ml of blood) or lithium heparin (1.8 mg/ml of blood). Squirting the sample through the needle is a poor practice, as it may cause severe disruption to the fragile blood cells. For general hematology analysis, EDTA is the anticoagulant of choice, as it is not possible to estimate fibrinogen or to count white blood cells accurately in heparinized samples.

In some avian species, however, storing blood samples in tubes containing EDTA causes progressive red cell hemolysis and is not recommended; in these cases, it is preferable to use heparinized tubes. This is the case with some species of Corvidae such as the jackdaw

Figs 22.1d-h | Small Birds - Basilic Vein

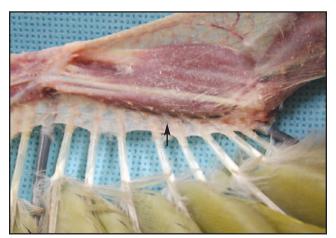

Fig 22.1d | The ventral surface of the wing of a cadaver with the covert feathers removed to show the location for superficial ulnaris vein lancing (arrow). Lancing the basilic vein in birds under 100 gms avoids subcutaneous hematomas and the possibility of death due to exsanguination. The site has a series of natural depressions over the vein that serve to allow the blood to pool. The depressions are formed by the insertion of the secondary feathers intermittently elevating and depressing the wing dermis just caudal to the border of the flexor carpi ulnaris muscle.

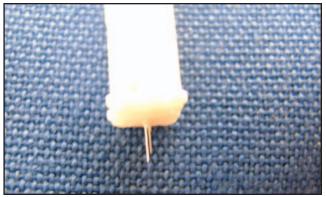

Fig 22.1f | Lancet with the cap removed and the 1 mm tip exposed.

Fig 22.1h | The superficial ulnaris vein has been lanced and blood is being drawn into a micro capillary tube. A cotton ball is applied to the site until hemostasis is achieved.

Fig 22.1e | Lancet used in a finger stick technique for blood sampling for glucose analysis in humans. The lancet still has the metal tip in place in the plastic cap.

Fig 22.1g | The lancet readied at the site to lance the superficial ulnaris vein.

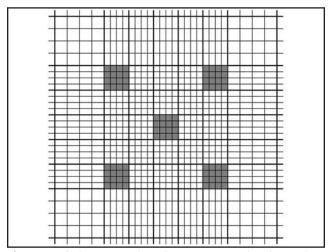

Fig 22.2a | The improved Neubauer counting chamber and the method for counting red blood cells. The total red blood cell count is performed by counting the number of cells contained in the 25 groups of 16 small squares (shaded) at the 4 corner squares and center square in the central area of the chamber. Closely ruled triple lines (illustrated in the drawing as thick lines) separate these squares.

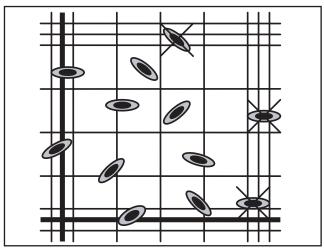

Fig 22.2b | The counting system. Count cells that touch the center triple line (seen here as a thick line) of the rules to the left and bottom; do not count cells that touch the center triple line of the rules to the right and top.

Table 22.2 | Special Considerations When Submitting **Blood Samples to a Laboratory**

- Seal the lid of the tube using waterproof tape in order to prevent any leakage.
- · Wrap the tube using an absorbent packing material, eg, cotton, to soak up any potential leakage and to protect it from breakage. Fasten it securely with tape, preferably commercially available printed tape with the legend "Pathological specimen. Fragile handle with care" or similar tape.
- · The tube should then be placed within two leak-proof plastic bags. Fasten the double wrapping securely with printed tape.
- Place submission form in a separate plastic bag.
- The package should then be placed within a postalapproved commercially available transport container made of aluminum, polystyrene, plastic or cardboard.
- Attach recipient and sender labels directly to the container using tape, or place container within a padded envelope and address it accordingly.

- Fibrinogen

(Corvus monedula) and raven (Corvus corax); Gruidae such as the black-necked crowned crane (Balearica pavonina) and gray-necked crowned crane (Balearica regulorum); Cracidae such as the black curassow (Crax alector); Phasianidae such as the brush turkey (Alectura lathami); Bucerotidae such as the crowned hornbill (Tockus alboterminatus); and the ostrich (Strutbio camelus).3,25 Storing blood samples in sodium citrate

tubes is recommended when sending samples to a commercial laboratory for processing using laser flow cytometry. 14,19

Commercially available collection tubes usually have printed labels. A pencil or ballpoint pen is used to enter the date and identification of the bird, preferably prior to filling the tube with the collected blood sample. Always remember the rule of thumb in clinical pathology: label tubes, not lids.

TRANSPORTATION OF BLOOD **SAMPLES**

In avian practice, hematology samples are commonly sent to commercial laboratories for processing (Table 22.2). Therefore, it is essential to be familiar with and to submit samples in full compliance with current local mail and courier regulations.

Hematology **Laboratory Analysis**

Although the hematology laboratory analysis described in this chapter were developed primarily for testing human blood and are in full compliance with the recommendations of the International Committee for Standardization in Hematology,34 these have been adapted and used successfully in avian hematology. Ideally, laboratory analysis should be carried out within 3 to 4 hours after collection. Many laboratories in the USA request that a smear be made immediately and sent along with the EDTA tube. If this is not possible, samples should be refrigerated at 8 to 12° C or within a suitable container for processing within 24 to 48 hours. Refrigerated samples are not ideal for hematology testing, as the cells invariably suffer some changes. Only an experienced hematologist would be able to differentiate these changes from true hemoresponses to particular medical disorders. Samples should not be exposed to extreme environmental conditions or excessive shaking, as this will affect the quality of the sample. Any form of mouth pipetting with a Thoma pipette or any other pipette with or without tubing is not acceptable within clinical laboratory practices.

The amount of blood available for testing from small birds (eg, <80 g) is very often limited, making it impossible to carry out a full range of analyses. The clinician should bear this in mind and request the analysis in order of priority (Table 22.3).

THE TOTAL RED BLOOD CELL COUNT (RBC X 1012/L)

The total red blood cell count is in itself an important hematology assay, but it also is essential for the estimation of mean corpuscular volume (MCV) and mean corpuscular hemoglobin (MCH). Many laboratories prefer to estimate RBC using an automatic system, as this is more precise than manual methods. The materials, solutions and method described in Table 22.4, together with Fig 22.2a,b, apply to a manual technique.

HEMOGLOBIN ESTIMATION (Hb g/dl)

In avian species, estimation of hemoglobin is hampered by the presence of nuclei in the erythrocytes. Hemoglobin estimation relies on the colorimetric measurement of hemoglobin released after the lysing of the erythrocytes. Hemoglobin can be estimated using automatic methods or manual methods (Table 22.5). Commercial laboratories that estimate hemoglobin using an automatic hematology analyzer have to take into consideration the photometric interference of the free nuclei after lysing of the erythrocyte. In the manual method, it is essential to remove the nuclei from the preparation because its presence could yield unreliable results. The nuclei can be deposited by low-speed centrifugation, but because some hemoglobin remains attached to the nuclei, colorimetric readings are commonly low. This can be overcome by estimating hemoglobin as cyanmethemoglobin using alkaline Drabkin's cyanide-ferricyanide solution or as oxyhemoglobin using ammonia solution. In both cases, the estimation is carried out using a spectrophotometer at the absorbance reading of 540 nm. A calibration graph should be made using commercially available hemoglobin standards to express hemoglobin as oxyhemoglobin. Conversely, hemoglobin can be estimated directly as oxyhemoglobin using a commercially available hemoglobinometer. This is the preferred method used and recommended by the author.

PACKED CELL VOLUME ESTIMATION PCV % (HEMATOCRIT Hct L/L)

Packed cell volume (PCV) is an important hematologic assay because it provides an easy and objective way of estimating the number of erythrocytes in the sample. It also is essential for the calculation of the mean corpuscular volume (MCV) and mean corpuscular hemoglobin concentration (MCHC). In avian species, PCV is best estimated using the microhematocrit method described (Fig 22.3). The use of plain microcapillary tubes is preferable, since the same tube can be subsequently used to estimate fibrinogen.

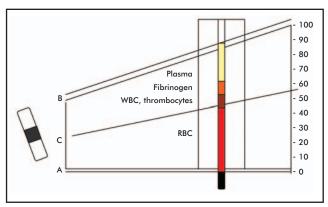

Fig 22.3 | Hematocrit reader and method for estimating packed cell volume. After centrifugation, position the capillary tube on the rack. Align tube (at the bottom, with the demarcation line between the sealing compound and the red blood cells) with line A. Slide the rack to the right or to the left, align the marginal meniscus at the top of the plasma column with line B. Position line C at the interface of the buffy layer and red cells, and read value on the scale.

Mean Corpuscular Values (Red Cell Absolute Values)

Mean corpuscular volume (MCV)

Mean corpuscular volume (MCV) is the expression of the average volume of individual erythrocytes calculated with the following formula:

 $MCV = (PCV \times 10)/RBC = MCV femto liters (fl)$

Mean corpuscular hemoglobin (MCH)

Mean corpuscular hemoglobin (MCH) is the expression of the average hemoglobin content of a single erythrocyte calculated with the following formula:

 $MCH = (Hb \times 10)/RBC = MCH picogram (pg)$

Mean corpuscular hemoglobin concentration (MCHC)

Mean corpuscular hemoglobin concentration (MCHC) is the expression of the volume within the erythrocyte occupied by the hemoglobin and is calculated with the following formula:

 $MCHC = (Hb \times 100)/PCV = MCHC (g/L)$

TOTAL WHITE BLOOD CELL COUNT (WBC X 10°/L)

The total white blood cell count (WBC) is one of the most important hematology assays in the assessment of health and disease in an individual. The WBC also is useful because it is used together with the differential white cell count to calculate the absolute number of each white blood cell within a blood sample. The materials, solutions and method described below, Table 22.6 and Fig 22.4, apply to the technique.

THE BLOOD FILM

The examination of stained blood films is the single most important assay in hematology analysis. An adequately

Table 22.4 | Manual Total Red Blood Cell (RBC) Count Hematology Test

Materials and Equipment

- · Automatic dispenser, 0-50 ml
- Disposable sample tube with lid, 5 ml
- Micropipette, 20 μ l and corresponding tip
- Roller mixer
- · Plain capillary tubes
- Improved Neubauer hemocytometer and coverslip
- · Laboratory lens tissue
- Petri dish 8.5 cm diameter
- Filter paper 8.5 cm diameter
- Toothpick
- Distilled water
- · Microscope, preferably with phase contrast capability

Test Systems

The Unopette 365851 system is probably the most popular method used for manual red blood cell count in avian species. It uses 10 μ l of whole blood in 1.9 ml of 0.85% saline, resulting in a 1:200 dilution. The two other commonly used systems are based on using either formol citrate solution (Dacie's fluid) or Natt and Herrick's solution, depending on whether the examination is carried out with or without phase contrast microscopy. Dacie's formol citrate solution is the least known diluting fluid, but one used and recommended by the author.

Working Solutions

- 1. BD Unopette 365851° red blood count manual hematology test
- Natt and Herrick's solution (for use without phase contrast microscopy)

NaCl	3.88 g
Na ₂ SO ₄	2.5 g
Na ₂ HPO ₄ 12 H ₂ O	2.91 g
KH ₂ PO ₄	0.25 g
Formaldehyde 40%	7.5 ml
Methyl violet 2B	0.1 g
Distilled water	to 1000 ml

Note: Allow solution to stand overnight. Filter before use.

3. Formol citrate solution or Dacie's fluid (for use with phase contrast microscopy)

Formaldehyde 10%	10 ml
Trisodium citrate	31.3 g
Distilled water	100 ml

Note: Refrigerate at 8 to 12° C.

Method

- · Label sample tubes using a permanent marker.
- Use an automatic dispenser to transfer 4 ml of either formol citrate solution or Natt and Herrick's solution into sample tube.
- Wait for 5 minutes to allow working solution to reach room temperature.
- Aspirate 20 μ l of whole blood from storage tube using micropipette, wipe side of pipette tip carefully using tissue and dispense on the side of sample tube to make a dilution of 1:200.
- Avoid touching the distal opening of the pipette tip with the tissue, as this will cause capillary shift of blood into the tissue.
- Avoid immersing the pipette tip into the diluting fluid.
 This is a poor laboratory practice.
- Place sample tube in roller mixer and wait for 3 minutes.
- Clean Neubauer hemocytometer and coverslip using a dry, lint-free cloth or laboratory lens tissue.
- Place coverslip onto hemocytometer and slide gently over it, making sure Newton's rings (colored interference pattern) appear on both sides of the contact surfaces.
- Withdraw a small aliquot of the diluted sample using a plain capillary tube.
- Fill up one side of the hemocytometer by touching gently the intersection between coverslip and hemocytometer with the loaded capillary tube. Avoid air bubbles and underfilling or overfilling.
- Place filter paper at the bottom of the Petri dish. Position two toothpicks on either side of the dish. Wet filter paper lightly with distilled water. Rest hemocytometer on toothpicks. Cover Petri dish. Leave for 5 minutes for the cells to settle down.
- The hemocytometer is now ready for use.
- Count cells contained in the four corner and central squares in the mid section of the hemocytometer.
 Following the "L" rule: count cells that touch the center triple line of the ruling on the left and the bottom sides; do not count cells that touch the center triple line of the ruling on the right and the top sides (see Figs 22.2a,b).
- Calculate red blood cell count using: $N/100 = RBC \times 10^{12}/L$

Note: N = number of cells counted in 160 small squares.

Table 22.5 | Hemoglobin Estimation

Materials and Equipment

- Automatic dispenser, 0-50 ml Toothpicks
- Disposable sample tube with lid, 5 ml
- Micropipette, 20 μ l and tip
- Roller mixer

- Cuvette, 10 mm²
- · Laboratory lens tissue
- Hemoglobinometer

Working Solution

Ammonia solution

Ammonia solution (0.88 specific gravity)	4 ml
Distilled water	to 1000 ml

Note: Refrigerate at 8 to 12° C.

Method

- Label sample tubes using a permanent marker.
- Use an automatic dispenser to transfer 4 ml of ammonia solution into sample tube.
- Wait for 5 minutes to allow working solution to reach room temperature.
- Aspirate 20 μ l of whole blood from storage tube using micropipette, wipe side of pipette tip carefully using tissue and dispense on the side of sample tube.
- · Avoid touching the distal opening of the pipette tip with the tissue, as this will cause capillary shift of blood into the tissue.
- Avoid immersing the pipette tip into the diluting fluid. This is a poor laboratory practice.
- Place sample tube in roller mixer and wait for 3 minutes.
- Decant approximately 3.5 ml of the diluted blood
- · Remove cell nuclei jelly using toothpicks.
- · Do not touch the clear reading walls of the cuvette with bare fingers.
- Clean clear reading walls of cuvette using laboratory lens tissue.
- · Zero hemoglobinometer using ammonia solution as blank.
- Reading expressed as Hb g/dl.

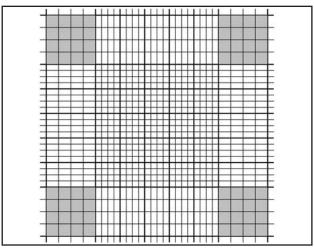

Fig 22.4 | Improved Neubauer counting chamber and the method for counting white blood cells. The total white blood cell count is performed by counting the number of cells contained in 4 groups (shaded areas) of 16 large squares at the four corner squares of the chamber. Closely ruled triple lines (illustrated in the drawing as thick lines) separate these squares.

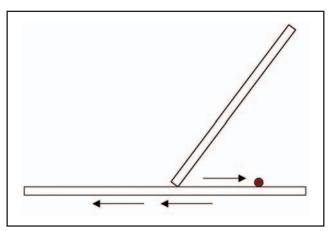

Fig 22.5 | The slide-to-slide technique. Move spreader slide backward to gently touch the drop of blood, allowing it to run across the edge of the slide. Move forward to make smear. Move slowly if blood runs slowly, move quickly if blood runs quickly.

prepared blood film provides the differential white blood cell count and absolute white blood cell count, the thrombocyte count and the hemoparasite examination.

Preparation of the Blood Film

Blood films can be made from a drop of fresh, non-anticoagulated blood directly from the tip of the syringe. Conversely, films can be made from blood stored in EDTA within 2 to 3 hours after collection. There are two generally accepted methods for the preparation of blood films in hematology: the slide-to-slide technique (Fig 22.5, Table 22.7) and the coverslip-to-slide technique (Fig 22.6, Table 22.8). A two cover-slip technique is not described here. The most popular method among avian

clinicians is the coverslip-to-slide technique, as smudging of blood red cells is generally minimized.

Fixation and Staining of the Blood Film

It is commonly accepted that blood films can be prepared and be fixed and stained at a later date. This is incorrect; blood films should at least be fixed immediately after preparation, particularly if made in a hot and humid environment or under cold and freezing conditions. Blood films should not be exposed to direct sunlight, moisture of any kind or vapor from chemicals (formaldehyde in particular), as this would invariably affect cell morphology.

Table 22.6 | Total White Blood Cell (WBC) Count Hematology Test

Materials and Equipment

- Automatic dispenser, 0-50 ml
- · Disposable sample tube with lid, 5 ml
- Micropipette, $100 \mu l$ and tip
- Roller mixer
- Plain capillary tubes

- Filter paper, 8.5 cm diameter
- Toothpicks
- Distilled water
- · Microscope, preferably with phase contrast capability

Test Systems

The Unopette 365877^d system was originally developed for the estimation of eosinophils in human hematology, but it has proved useful for determining the total white cell count in avian species. This system uses 25 μ l of whole blood into 0.775 ml of 1% Phloxine B diluent resulting in a 1:32 dilution, and is the system used by most practitioners in the USA.^{3,19} The method described below is based on the use of ammonium oxalate solution, which is the method used and recommended by the author.

Working Solutions

- BD Unopette 365877^d eosinophil count manual hematology test^d
- 2. Ammonium oxalate solution 1%

Ammonium oxalate	10 g	
Distilled water	to 1000 ml	

Note: Refrigerate at 8 to 12° C.

Method

- Label sample tubes using a permanent marker.
- Use an automatic dispenser to transfer 1.9 ml of 1% ammonium oxalate solution into sample tube.
- Wait for 5 minutes to allow working solution to reach room temperature.
- Aspirate 100 µl of whole blood from storage tube using micropipette, wipe side of pipette tip carefully using tissue and dispense on the side of sample tube.
- Avoid touching the distal opening of the pipette tip with the tissue, as this will cause capillary shift of blood into the tissue.
- Avoid immersing the pipette tip into the diluting fluid.
 This is a poor laboratory practice.
- Place sample tube in roller mixer and wait for 3 minutes.
- Clean Neubauer hemocytometer and coverslip using a laboratory lens tissue or dry, lint-free cloth.
- Place coverslip onto hemocytometer and slide gently over it, making sure Newton's rings (colored interference pattern) appear on both sides of the contact surfaces.
- Withdraw a small aliquot of the diluted sample using a plain capillary tube.
- Fill up one side of the hemocytometer by gently touching the intersection between coverslip and hemocytometer with the loaded capillary tube. Avoid air bubbles and underfilling or overfilling.
- Place filter paper at the bottom of the Petri dish. Position two toothpicks on either side of the dish. Lightly wet filter paper with distilled water. Rest hemocytometer on toothpicks. Cover Petri dish. Leave for 5 minutes for the cells to settle down.
- The hemocytometer is now ready for use.
- Count cells contained in the four outer large squares of the hemocytometer.
- Calculate total white blood cell count using:
 N/20 = WBC x 10°/L

Note: N = number of cells counted in 64 small squares.

Table 22.7 | Method for Slide-to-Slide Technique

- It is highly recommended to use one-end-frosted microscopic slides to easily note the ID of the sample on the slide using a pencil.
- Wipe slides clean with a lens tissue or lint-free cloth.
- Use a plain microcapillary tube to withdraw a small amount of fresh, non-anticoagulated blood directly from syringe tip or EDTA tube.
- Place a small drop of blood (2 μ l) at one end of a slide.
- Select a spreader slide and position it in front of the drop of blood at about a 45° angle. The selected slide should be free from any indentation. To test this, pass the spreading edge over the edge of a fingernail.
- Gently move the spreader slide backward to touch the drop of blood and allow the blood to run across the edge of the slide.
- Gently drive the slide forward with a steady but firm movement to create a uniform smear.
- It is always a good practice to make two good-quality blood films.

Table 22.8 | Method for Coverslip-to-Slide Technique

The only significant difference between this method and the previous one consists of the following steps:

- Place a large rectangular coverslip over the drop of blood.
- Pull the coverslip and the slide in opposite directions in a steady but firm movement to create a uniform smear.

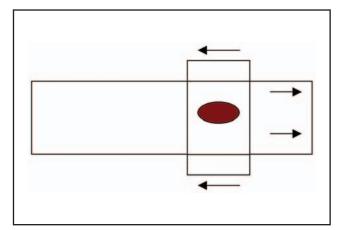

Fig 22.6 | The coverslip-to-slide technique. Place coverslip onto drop of blood. Apply gentle pressure downward. Move slide and coverslip in opposite directions to make smear.

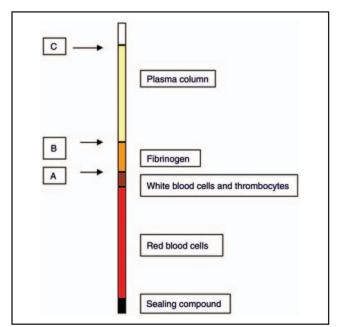

Fig 22.7 | A microcapillary tube after incubation and centrifugation, and the measurements necessary for the estimation of fibrinogen.

Fixation

In general, freshly prepared blood films should be immersed in absolute methanol within a Coplin jar for 5 to 10 minutes immediately after preparation. Fixed blood films can then be stored within commercially available slide storage boxes (eg, under field conditions) and be stained at a later date. Blood films also can be stained immediately after fixation.

The importance of adequate fixation of blood films from avian species cannot be overemphasized. The intracytoplasmic granules of the heterophils and basophils are water soluble; therefore, blood films should be adequately fixed before staining in order to preserve the integrity of these structures. A significant problem in avian hematology is the presence of smudged red cell nuclei as a consequence of hemolysis in poorly fixed blood films. This is one of the main reasons why clinicians and commercial laboratories are now inclined to use stains that are prepared in absolute methanol (eg, Wright-Giemsa stain, Leishman stain) and are used at full strength so films are fixed and stained at the same time. If absolute methanol within a Coplin jar is used for fixation in your laboratory, it must be replaced as soon as it begins showing chemical fatigue. This would depend on the number of slides fixed and the environmental conditions within the laboratory.

Staining

Most Romanovsky stains used for staining human and mammalian blood films are suitable for staining avian blood films. However, the results obtained with various stains may be slightly different, and the selection of stains is generally accepted as a matter of personal preference. Commonly used stains include Wright stain, Giemsa stain, Wright-Giemsa stain, Leishman stain, Wright-Leishman stain, May-Grünwald stain and May-Grünwald-Giemsa stain. In the author's opinion, rapid stains on their own, eg, Diff Quick and Rapid Diff, do not produce adequate quality for the differentiation of subtle blood cell structures and those of hematozoa. This is particularly important with respect to the morphological characteristics of the granulocytes.

Automatic slide stainers facilitate staining a relatively large number of blood films at the same time, producing consistent results and eliminating variations that may occur with manual techniques. However, this type of equipment is relatively expensive to purchase and maintain and is more appropriate for high-volume commercial laboratories.

It is important that clinicians or laboratory technicians recall the basic principles of hematology when staining blood films. The pH of the stains should be checked each time new stock is prepared. Some stains, particularly those prepared from powder, should be adequately filtered. Glassware should be properly washed, rinsed with distilled water and dried thoroughly before use. Many of the common artifacts on blood films are due to careless preparation and improper methodology.

The staining method currently used and recommended

Table 22.9 | Wright-Giemsa Staining Procedure

Working Stain

- 3 g Wright stain powder
- 0.3 g Giemsa stain powder
- 5 ml glycerol
- To 1000 ml absolute methanol (acetone free)
- · Filter and store

Method

- Prepare thin blood smears.
- · Place on staining rack.
- Flood smear with Wright-Giemsa stain, allow to stand for 3 minutes.
- Add equal amount of Sørensen's pH 6.5-6.8 buffer, depending on batch stain.
- Mix gently by blowing using a pipette until metallic green sheen forms on the surface, allow to stand for 6 minutes.
- Rinse with buffer, allowing to stand for 1 minute for differentiation.
- Wash copiously with buffer.
- Wipe the back of smear with tissue to remove excess stain.
- Prop in rack until dry.

by the author is a slightly modified technique⁴ described in Table 22.9.

The placement of a coverslip using a commercially available mounting medium over the blood smear is optional. Additionally, the mounting of blood films offers several advantages such as preventing scratching during transport, protection against damage during excessive manipulation (eg, teaching material) and enhancing visualization for optimal examination and photography.

Morphologic and Staining Characteristics of Red Blood Cells, White Blood Cells and Thrombocytes

Normal red blood cells appear elliptical and have elliptical nuclei; the cytoplasm stains uniformly eosinophilic, and the nuclei is dark purple in color (modified Wright-Giemsa stain).

In general, the widely known "Romanovsky stains" contain blue azure that reacts with acid groups, including those of nucleic acids and proteins of the nucleus and cytoplasm and eosin Y, which has a particular affinity for basic groups of hemoglobin. When used in different avian species, the slight variations observed may be the result of true species diversity or simply variations in the materials and methods used from individual to individual or from laboratory to laboratory.

Adequate knowledge of the morphology and staining characteristics of the different blood cells is of the utmost importance for the differentiation and classification of those blood cells (Table 22.10 and Figs 22.8-22.43).

Table 22.10 | Morphologic and Staining Characteristics of Different Blood Cells

Blood Cell	Morphologic Characteristics	Staining Characteristics	
Erythrocyte	Mature cells		
	Medium size, oval elon- gated shape, central oval elongated nucleus	Cytoplasm: uniform pale orange to red-pink; Nucleus: purple-red, condensed, clumped chromatin	
	Immatu	re cells	
	Smaller than mature cell, round to semi-oval, relatively larger nucleus	Polychromatic, cytoplasm pale to dark blue	
Heterophil	Medium size, round shape, bilobed nucleus	Colorless cytoplasm, rod- to cigar-shaped brick red to pale blue granules	
Eosinophil	phil Medium size, round shape, bilobed nucleus Pale blue cyto oval brich blue granul		
Basophil	Small size, round shape, unlobed nucleus	Pale blue cytoplasm, vari- able number of small, medium and large dark red-purple granules	
Lymphocyte	Small to medium size, typically round to triangular shape, centrally positioned large round nucleus; in general, 25 cytoplasm:75 nucleus; ratio, coarsely condensed to highly condensed chromatin	Pale blue cytoplasm	
Monocyte	Large size, typically round shape, eccentrically positioned kidney-shaped nucleus; in general 75 cytoplasm:25 nucleus ratio, cytoplasm lace-like appearance, often medium size vacuoles, coarsely condensed chromatin	Cytoplasm pale blue to pale gray	
Thrombocyte	Small, oval to rectangular shape, nucleus oval to rectangular	Cytoplasm colorless to pale blue, large vacuoles, nucleus highly condensed dark purple-red chromatin	

Differential White Blood Cell and Absolute White Blood Cell Count

For the differential white blood cell count and absolute white blood cell count, the film should be examined thoroughly under high-power magnification, under oil (1000x). The recommended topographic site is on the shoulder of the blood film. The *shoulder* is the edge of the oval-shaped end of a smear. This is the area where the blood cells are in one layer and are slightly segregated, thus facilitating examination.

In general terms, 100 white blood cells should be counted and classified according to the morphologic and staining characteristics. Counting is usually carried out using a commercially available manual or electronic differential cell counter. The differential white blood cell count is expressed as a percentage of the individual cell group. The percentage of each cell group is then converted into absolute numbers by reference to the total WBC using the following formula:

Thrombocyte Count

Thrombocytes are usually counted while performing the differential white blood cell count. Valid and reliable results cannot be obtained if there is evidence of thrombocyte clumping.

The absolute number of thrombocytes is estimated by using the following formula:

(No. of thrombocytes counted/100) x WBC = thrombocytes x $10^9/L$

Figs 22.44-22.48 and Tables 22.12-22.18 are offered as references for interpreting hemotological findings.

FIBRINOGEN ESTIMATION (g/L)

Fibrinogen is a plasma protein essential for normal blood coagulation, but also is one of the acute reactive proteins that are detected in increased levels in association with medical disorders involving infection and inflammation (see Tables 22.11, 22.12 and 22.18).

Hemoparasite Examination

Hemoparasite examination is carried out on thin, good-quality blood films. Prior to a differential white cell count using high-power magnification (1000x), the blood film should be examined under low-power magnification (eg, 200x or 400x) in order to detect large extra cellular hemoparasites (eg, microfilariae), which could be missed if the film is examined only under high-power magnification. The examination under low-power magnification should concentrate on areas not commonly examined under high-power magnification, eg, head and tail of the blood smear. The blood film should be examined in full in a systematic way and following a consistent pathway.

A blood parasite quantitative assessment should be carried out, in certain cases and under certain circumstances, by examining 1000 red cells (in the case of intracytoplasmic parasitic forms) and determining the

Table 22.11 | Fibrinogen Estimation

Materials and Equipment Needed for Fibrinogen Estimation

- Microcapillary tube rack
- · Microhematocrit centrifuge
- Microhematocrit reader
- Water bath 56 $^{\circ}$ C \pm 1 $^{\circ}$ C
- Microcapillary tube holder
- Microscope with measuring eyepiece and stage Vernier scale
- Timer

Method (following estimation of packed cell volume)

- Place microcapillary tube in tube rack.
- Place loaded rack in water bath at 56° C for 3 minutes (make sure the entire plasma column is immersed).
- Centrifuge microcapillary tubes again at 10,000 to 12,000 "g force" for 5 minutes.
- Place microcapillary tubes in tube holder and, using the microscope measuring eyepiece and the stage Vernier of the microscope, take reading at the upper and lower limits of the protein layer and at the upper limit of the plasma column (see Fig 22.7).
- Estimate fibrinogen with the following formula:
 (B A)/(C A) x 100 = fibrinogen g/L

Note: It is essential to perform this analysis on blood stored in EDTA because the analysis would be invalidated if performed on samples stored in heparin or on samples containing clots.

number of red cells containing hemoparasites (eg, *Haemoproteus* spp., *Babesia* spp.). The number is then expressed in percentage and this usually constitutes the degree of parasitemia.

If hemoparasites are observed during routine examination of the blood film under low- or high-power magnification, it is imperative to immediately prepare additional blood films. Ideally, a fresh blood sample should be obtained to prepare these new blood films from non-anticoagulated blood. This is of the utmost importance if a rare parasite is observed in the film. Blood films should be fixed but unstained when sending them to parasitologists, who have their own preferences for stains and staining procedures.

Unless specified otherwise, hematology images are from a saker falcon (Falco cherrug):

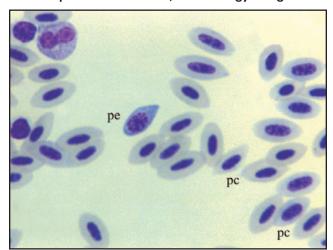

Fig 22.8 | Shown is a polychromatic erythroblast (pe) and poikilocytes (pc). The nuclear chromatin of the polychromatic erythroblast is clumped and the cytoplasm is highly basophilic (modified Wright-Giemsa stain).

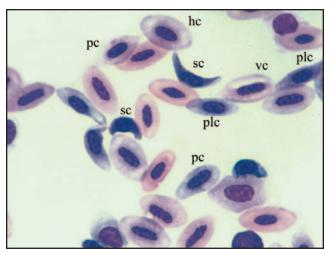

Fig 22.10 | The red cells in sickle cell anemia show sickling (sc), vacuolation (vc), hypochromia (hc) and polychromasia (plc). Some poikilocytes (pc) also are present (modified Wright-Giemsa stain).

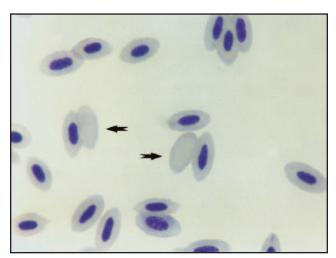

Fig 22.12 | Erythroplastid (arrows) forms (modified Wright-Giemsa stain).

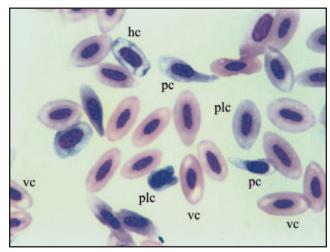

Fig 22.9 | The red cells in a bird with severe anemia show vacuolation (vc), hypochromia (hc) and polychromasia (plc). There are some poikilocytes (pc) in the smear (modified Wright-Giemsa stain).

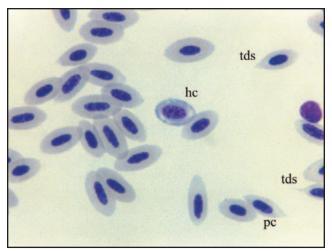

Fig 22.11 | Hypochromic (hc), teardrop-shaped red cells (tds) and poikilocytes (pc) are illustrated (modified Wright-Giemsa stain).

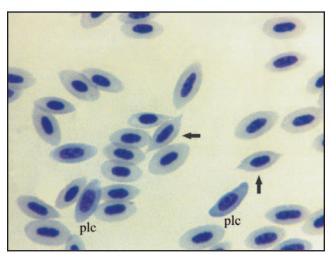

Fig 22.13 | Poikilocytes (arrows) are seen in metabolic defects and increased erythropoiesis. Polychromatic red cells (plc) are produced in response to severe blood loss. These are larger than normal cells (modified Wright-Giemsa stain).

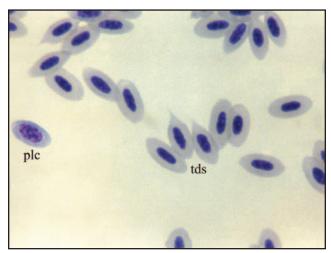

Fig 22.14 | Shown are teardrop-shaped red cells (tds) and polychromasia (plc). Teardrop-shaped cells are indications of toxicosis (May-Grünwald Giemsa stain).

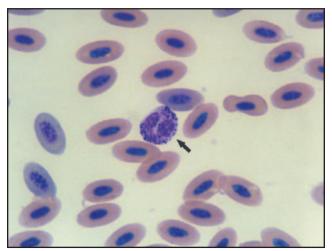

Fig 22.16 | In this eosinophil (arrow), note the numerous small and medium-sized, dark purple-colored granules located mainly in the periphery of the cytoplasm (modified Wright-Giemsa stain).

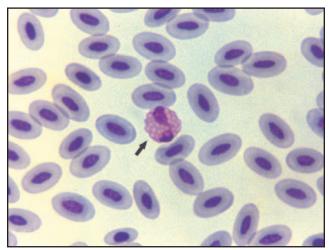

Fig 22.18 | An eosinophil (arrow) from a kori bustard (*Ardeotis kori*). Note the large, round, orange-colored granules characteristic of this species (May-Grünwald Giemsa stain).

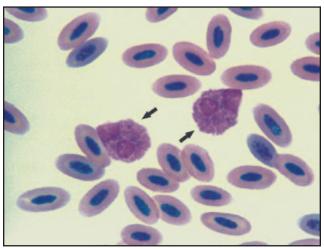

Fig 22.15 | Two normal heterophils (arrows). Heterophils are characterized by brick red, elongated intracytoplasmic granules and bilobed nuclei (modified Wright-Giemsa stain).

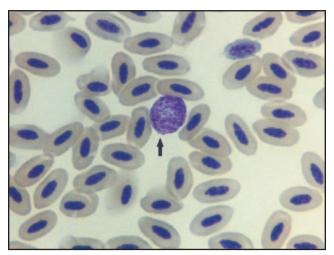

Fig 22.17 | An eosinophil (arrow) from an eclectus parrot (*Eclectus roratus*). Note the numerous small intracytoplasmic granules widespread across the cytoplasm. The granules stain dark purple in color (modified Wright-Giemsa stain).

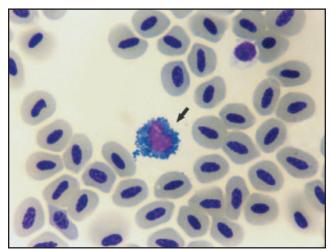

Fig 22.19 | A slightly disrupted eosinophil (arrow) from a lesser sulphur-crested cockatoo (*Cacatua sulphurea*). The medium-sized, round granules are blue in color (May-Grünwald Giemsa stain).

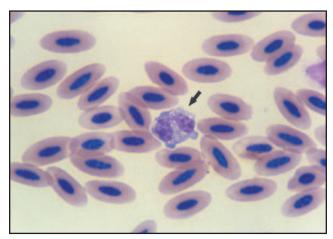

Fig 22.20 | In this eosinophil (arrow) from a saker falcon (*Falco cherrug*), the granules are not stained, giving the impression of numerous irregular vacuoles within the cytoplasm (May-Grünwald Giemsa stain).

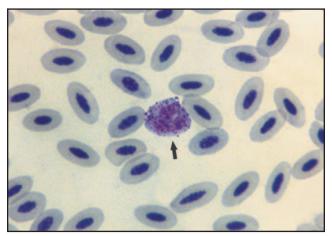

Fig 22.22 | These eosinophil (arrow) granules are well stained, irregular in shape and size, stained purple or dark purple (modified Wright-Giemsa stain). The author highly recommends the use of this stain for routine hematology.

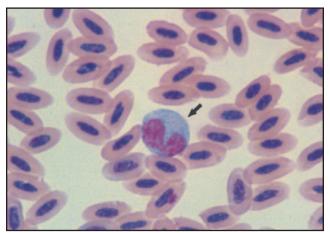

Fig 22.24 | A normal monocyte (arrow) is a relatively large cell with a kidney-shaped nucleus and abundant, slightly opaque, blue-gray, "lace-like" cytoplasm (modified Wright-Giemsa stain).

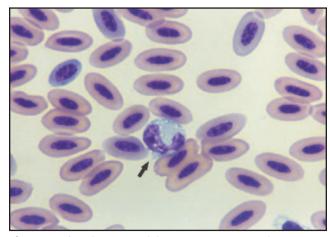

Fig 22.21 | In this eosinophil (arrow) is seen a similar-staining artifactual difference, as in the previous figure. The granules are not stained, giving the impression of numerous vacuoles within the cytoplasm (Diff Quik stain).

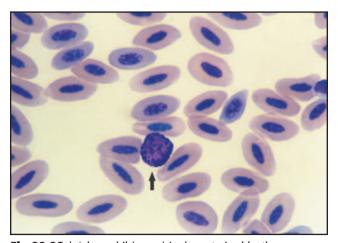

Fig 22.23 | A basophil (arrow) is characterized by the presence of large, round, dark purple granules widespread across the cytoplasm and an unlobed nucleus (modified Wright-Giemsa stain).

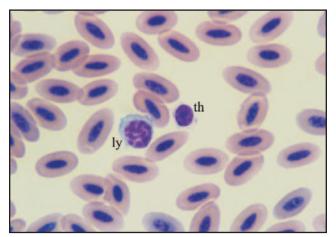

Fig 22.25 | A normal lymphocyte (ly) and a normal thrombocyte (th). Lymphocytes are regular round cells with a central or slightly eccentric nuclei, and with a varying amount of pale blue cytoplasm (modified Wright-Giemsa stain).

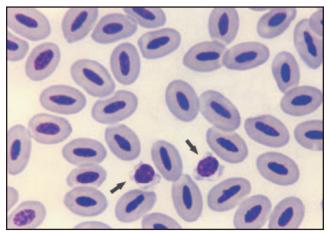

Fig 22.26 | Two normal thrombocytes (arrows) from a kori bustard (Ardeotis kori). Thrombocytes are round or irregular cells with completely dark purple and dense round or oval nuclei, and clear blue-gray cytoplasm. In some species, a few cytoplasmic projections can be observed. Sometimes it can be very difficult to differentiate between thrombocytes and small lymphocytes (May-Grünwald Giemsa stain).

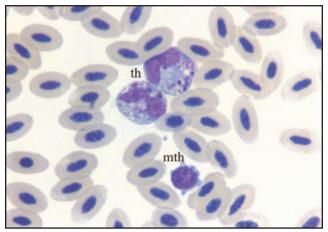

Fig 22.28 | Two toxic heterophils (th) and a megathrombocyte (mth). One of the heterophils shows a lack of lobulation of the nucleus (left shift); both show loss of granulation and the cytoplasm is stained basophilic. The megathrombocyte is significantly larger than a normal thrombocyte. The cytoplasm is basophilic, the nucleus cytoplasm ratio is increased and it has scalloped cytoplasmic margins (modified Wright-Giemsa stain).

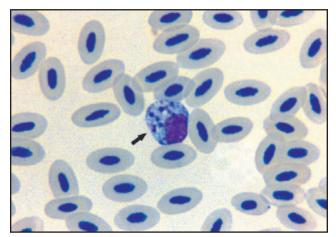

Fig 22.30 | A toxic heterophil (arrow) with a lack of nuclear lobulation (left shift) and loss of cytoplasmic granulation. Only a few large, round, dark purple granules are present and the cytoplasm is basophilic (modified Wright-Giemsa stain).

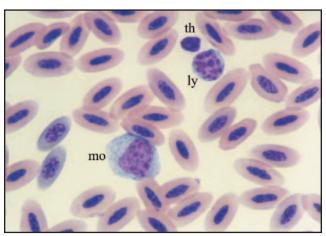

Fig 22.27 | Shown are a normal thrombocyte (th), normal lymphocyte (ly) and a normal monocyte (mo) for comparison of three different mononuclear cells. Thrombocytes and small lymphocytes can be very similar. In order to differentiate between them, the appearance of the nuclear chromatin has to be closely examined (modified Wright-Giemsa stain).

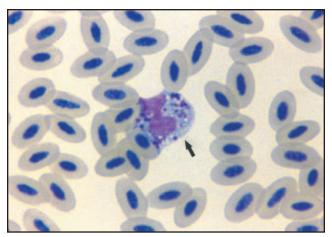

Fig 22.29 | A toxic heterophil (arrow) showing loss of nuclear lobulation (left shift) and loss of cytoplasmic granulation. The granules are round, large and stained dark purple, and the cytoplasm is basophilic (modified Wright-Giemsa stain).

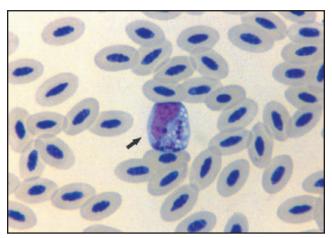

Fig 22.31 | A toxic heterophil (arrow). The heterophil shows loss of nuclear lobulation (left shift) and loss of cytoplasmic granulation. There are very few large, dark purple granules and the cytoplasm is basophilic (modified Wright-Giemsa stain).

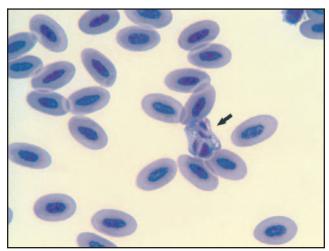

Fig 22.32 | A toxic heterophil (arrow). The nucleus is segmented into several fragments (right shift); the granules are not stained, giving the impression of numerous vacuoles within the cytoplasm (May-Grünwald Giemsa stain).

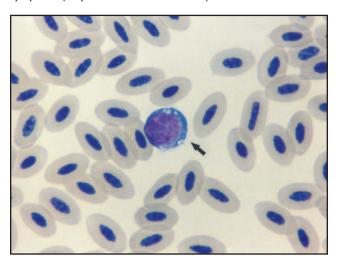

Fig 22.34 | A toxic monocyte (arrow). The nuclear/cytoplasm ratio is increased, the cytoplasm stains basophilic and there are numerous vacuoles within the cytoplasm (modified Wright-Giemsa stain).

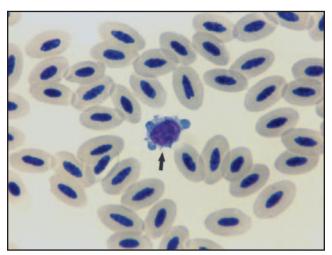

Fig 22.36 | A megathrombocyte (arrow). Megathrombocytes are larger than normal thrombocytes and can be confused with small lymphocytes. The cytoplasm of megathrombocyte stains basophilic and the nuclear chromatin is coarser (modified Wright-Giemsa stain).

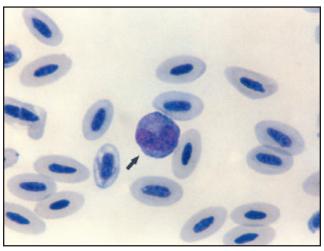

Fig 22.33 | A reactive monocyte (arrow). The cytoplasm is basophilic and the nuclear chromatin is coarse (modified Wright-Giemsa stain).

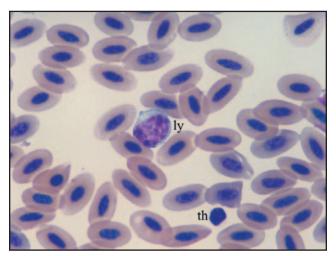

Fig 22.35 | A normal lymphocyte (ly) and a normal thrombocyte (th) (modified Wright-Giemsa stain).

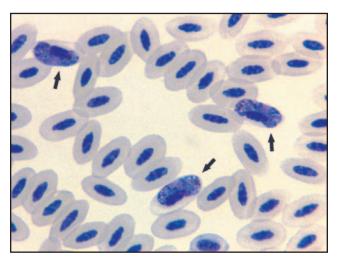

Fig 22.37 | Haemoproteus tinnunculi (arrows) (modified Wright-Giemsa stain).

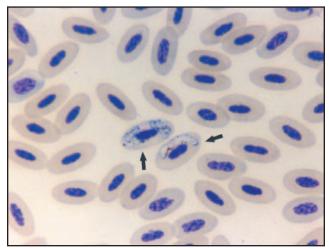

Fig 22.38 | Haemoproteus psittaci (arrows) from a greenwinged macaw (Ara chloroptera).

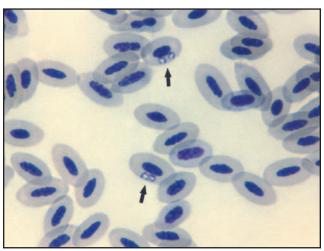

Fig 22.39 | Babesia shortti (arrows) (modified Wright-Giemsa stain).

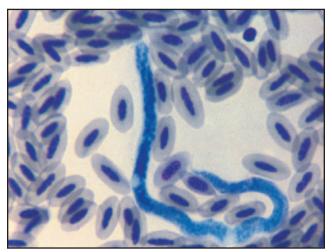

Fig 22.40 | Microfilaria sp. (modified Wright-Giemsa stain).

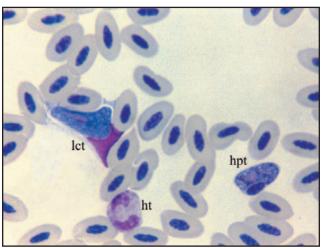

Fig 22.41 | Leucocytozoon toddi (lct), Haemoproteus tinnunculi (hpt) and normal heterophil (ht) (modified Wright-Giemsa stain).

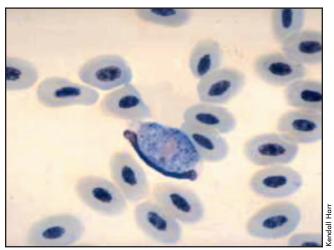

Fig 22.42 | Leucocytozoon simondi from a Canada goose (Branta canadensis).

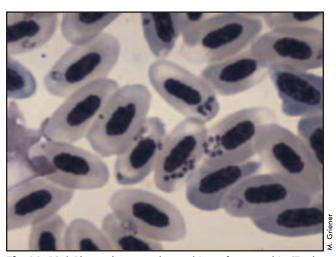

Fig 22.43 | Plasmodium vaughani schizont from a robin (Turdus migratorius).

Age-related Hematologic Changes

Age-related hematologic findings in kori bustard (*Ardeotis kori*) chicks during their growth and development are presented (Figs 22.44-22.48). Blood samples were collected from 16 clinically normal chicks at 1-month intervals. The tenth sampling was obtained at 15 months of age.

The following is a collection of hematology values and an interpretation guide for the avian veterinarian:

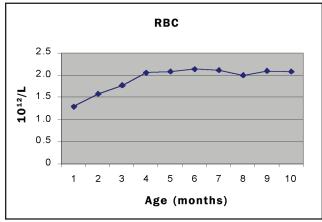

Fig 22.44 | The RBC increased steadily for the first 4 months from 1.28 \pm 0.06 x 10¹²/L at 1 month of age, increasing gradually up to the age of 4 months to 2.06 \pm 0.08 x 10¹²/L. After this time, the RBC remained fairly constant. The RBC value at the age of 12 to 15 months was 2.08 \pm 0.06 x 10¹²/L.

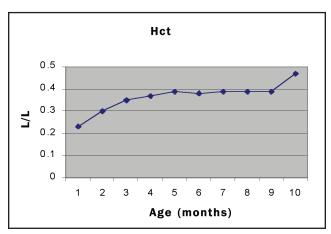

Fig 22.46 | The Hct value continued to increase steadily from 0.23 \pm 0.7 L/L at 1 month of age to 0.399 \pm 0.9 L/L at 5 months of age and remained fairly constant until the age of 12 to 15 months, when the value increased to 0.47 \pm 0.9 L/L.

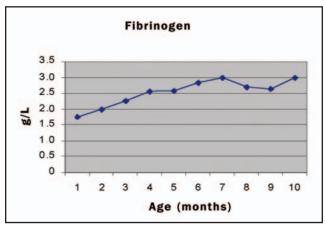

Fig 22.48 | The fibrinogen value was 1.76 \pm 0.18 g/L at 1 month of age, increasing steadily to 3.0 \pm 0.2 g/L at the age of 7 months.

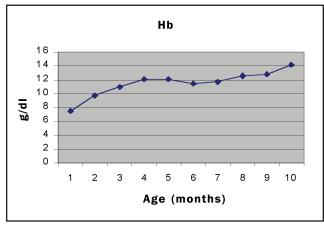

Fig 22.45 | The HB value followed a similar pattern as for RBC, with a value of 7.5 \pm 0.2 g/dl at the age of 1 month, increasing to 12.1 \pm 0.3 g/dl at 4 months of age. This value remained fairly constant until the age of 12 months, when it increased to 14.2 \pm 0.4 g/dl.

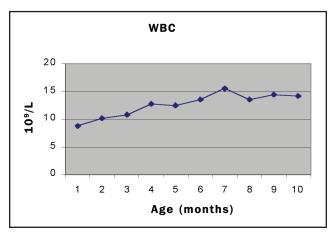

Fig 22.47 | The WBC count at 1 month of age was $8.78 \pm 0.45 \times 10^{9}$ /L, increasing to $15.6 \pm 0.7 \times 10^{9}$ /L at 7 months, then decreasing slightly to $14.5 \pm 0.5 \times 10^{9}$ /L at 9 months of age.

Hemoresponses

WBC, DIFFERENTIAL WHITE BLOOD CELL COUNT

Table 22.12 | Evaluating the RBC, HB, PCV and Red Cell Indices

Hematologic Findings	Possible Causes
Polycythemia: Increased packed cell volume (PCV) or hematocrit (Hct) and red blood cell count (RBC)	Absolute: Primary polycythemia Polycythemia vera Secondary polycythemia, reaction to hypoxia Physiological: Adaptation to high altitudes Pathological: Chronic circulatory or respiratory disease (ie, COPD or asthma of macaws), iron storage disease, rickets Hypoxic increase in erythropoietin production Non-hypoxic, autonomous increase in erythropoietin production
	Relative: Dehydration, different etiologies
PCV >56% or Hct >0.56 L/L	Dehydration in most birds, relatively normal in small (<100 g) psittacine and passerine birds, especially cockatiels
Anemia: Decreased PCV or Hct and RBC	Absolute: Hemorrhage (trauma, coagulation disorders, ectoparasitism, endoparasitism); increased red cell destruction (hemoparasites, some bacterial infections, autoimmune hemolytic anemia); decreased red cell production (nutritional deficiencies, chronic infection, chronic renal disease, avian leukoses, toxicosis)
	Relative: Overhydration
Low hemoglobin (Hb) value: (eg, <11.0 g/dl)	Anemia in adult birds
Low mean corpuscular hemoglobin concentration (MCHC) value: (eg, <29.0 g/dl)	Possible iron and other element deficiency

Table 22.13 | Evaluating the Leukocytosis/Toxic Heterophilia with Left Shift

Monocyte Count	Possible Causes
Normal	Infectious Acute: Gram-negative septicemias. Tuberculosis (granulomas in Falconiformes and Galliformes, but not in Psittaciformes, in these species exclusive accumulation of epithelioid cells [Gerlach, personal communication, 2002]), coligranulomatosis, salmonellosis, yersiniosis and pasteurellosis
Monocytosis	Fungal: Aspergillosis, severe candidiasis Parasitic: Trichomonaisis, capillariaiasis, maggot infestations Miscellaneous: Foreign body inhalation pneumonia, focal peritonitis, chronic ulcerative lesions, old open wounds Acute and chronic: Pox and herpesvirus infections, chlamydophilosis Chronic: Granulomatous or purulent infections/ infestations
Monocytopenia	Non-infectious Maggot infestation, burns, lead/smoke intoxication, egg yolk peritonitis

Table 22.15 | Evaluating Leukocytosis/Heterophilia/ **Normal Heterophils**

Monocyte Count	Serial Sampling	Possible Causes of Hemogram Changes
Monocytosis	WBC reduced	Healing of soft tissue damage or bone fractures without the complications of severe infec- tion or necrosis, relative cell numbers depend on the degree of chronicity
Normal monocyte count	WBC stays elevated	Acute or chronic inflammation without severe tissue necrosis
	Return to normal within 24-72 hours in the absence of stressor	Stress

Note: Monocytes are slow-reacting cells of the immune system, still changing when other values are already close to normal levels.

Table 22.14 | Evaluating the Leukocytosis/Toxic Heterophilia with Left Shift (cont)

<u>-</u>	reieropiinia wiiii zeii oiiii (coiii)					
WBC and Differential	Monocyte Count	Humoral Cellular Response to Continued Presence of Pathogen	Prognosis			
Normal WBC/toxic heterophils and/or reactive lymphocytes	Normal monocyte count - acute	Additional abnormal- ities-immature cells (left shift), anemia, bone marrow damage, excessive demand	Poor			
	Monocytosis - chronic anemia due to bone marrow damage = depression/aplastic anemia	No additional abnormalities	Excellent			

Note: Causes for bone marrow suppression and anemia include infections such as viral, bacterial endotoxins in gram-negative septicemia, neoplastic, toxic such as lead toxicosis, metabolic such as high estrogen

Table 22.16 | Evaluating Lymphocytosis with Reactive Lymphocytes (seen rarely in species with a strong heterophilic leukogram)

Hematologic Findings	Possible Causes
Premature lymphoid cells, mitotic figures, anemia	Lymphoid leukosis; marked lymphocytosis with or without immature cells indicates lymphocytic leukemia, while marked lymphocytosis with predominantly mature, small lymphocytes with scalloped cell margins indicates lymphoid neoplasia
Blood parasites with or without lymphocytosis and/or anemia	Haemoproteus and Leucocytozoon spp. usually without manifesting clinical signs with the exception of young birds; Babesia, Plasmodium spp. may cause life-threatening condition with severe anemia and in some cases lymphocytosis
Monocytosis	Strong chronic stimulation of the immune system, eg, chronic inflammation, chronic viremias (leukopenia, lymphocytosis in chronic viral antigen exposure), chronic aspergillosis, immune-mediated diseases

Table 22.17 | Evaluating Leukopenia

Hematologic Findings	Possible Causes
Toxic heterophils, immature cells, anemia, monocytosis, reactive lymphocytes	Final stage of immune response, severe bone marrow damage, gram-negative septicemia, infected wounds, circovirus in psittacines, marked loss of skin, eg, burns, marked tissue necrosis, smoke intoxication. Grave prognosis.
Normal morphology, relative heterophilia, absolute lymphopenia	Initial stage of stress
Reactive lymphocytes, relative lymphocytosis, progressive or intermittent leukopenia	Acute viral infection (toxic heterophils in pox and herpesvirus infections)

Dedication

This chapter is dedicated to Dr. Christine M. Hawkey.

Acknowledgments

The author thanks HRH Prince Fahad bin Sultan bin Abdulaziz Al Saud for his support to the advancement of falcon medicine, and to Mr. Basil Al Abbasi, Director General, for his continuing interest in the clinical and research program of the Falcon Specialist Hospital and Research Institute; to Shinto K. John; Generoso Quiambao; Dr. Jesus Naldo.

Diagnostic Value of

Biochemistry

KENDAL E. HARR, DVM, MS, Dipl ACVP

Fig 23.1 | A normal serum sample on the left and a lipemic sample on right.

Clinical chemistry, along with hematology and physical examination, is the cornerstone of medical diagnosis of disease in any species. Plasma biochemistry is especially important in avian species, which frequently show minimal overt clinical signs of disease, even when seriously ill. Veterinarians, therefore, need accurate and useful biochemical analysis to successfully diagnose and treat avian species. The Clinical Laboratory Improvement Amendments (CLIA) are the federal laws and regulations that govern human diagnostic laboratories. No such governing policy exists in veterinary diagnostic medicine. This results in variable methodology, protocol, and most importantly, quality control, between veterinary laboratories. It falls to the veterinary clinician to ensure that the diagnostic laboratory being used maintains a high standard of quality control and that results are accurate. The clinician should develop a working relationship with the laboratory of choice and must continually monitor results for possible inaccuracy and error. Feedback to the laboratory must occur to ensure that the laboratory personnel are aware of any errors and can correct them. The laboratory used should be familiar with handling avian samples. Modified techniques in the laboratory, such as the use of 10-µl microhematocrit tubes, pediatric sample cups and dilution, can extend the sample and allow more data to be collected, especially from the smaller avian patient. When choosing a laboratory, the clinician also should consider its location, transport issues and delayed processing of the sample. All of these can cause artifactual change in the sample and decrease ability to diagnose disease.

Concentrations of analytes represent a steady state of input, consumption and partitioning. The body is always in flux. Generally, pathologic conditions cause either an increased or decreased concentration of various analytes. However, if both input and consumption are

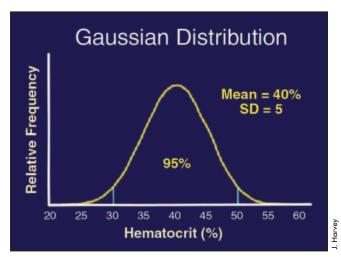

Fig 23.2 | 2.5% of the population is eliminated on each side of the curve to generate a 95% reference interval. This increases the likelihood that diseased patients are flagged as abnormal. It also means that it is quite likely that a healthy patient will have one analyte that is mildly abnormal.

decreased or increased at the same time, the concentration may remain in the normal reference interval even though the patient is very ill. For example, the globulin fraction may remain within the normal reference interval in a bird with marked enteritis because of increased production of acute phase inflammatory proteins and antibodies with concurrent loss of protein through a compromised gastrointestinal tract. Interpretation of clinical chemistries must therefore be done on a case-by-case basis with knowledge of species-specific physiology.

In comparison to domestic species, it can be a challenge to simply ascertain normal reference intervals for avian patients. Reference intervals for biochemical analytes are highly dependent on the machines, reagents and methods used, and may vary significantly between different laboratories. According to CLIA, each human diagnostic laboratory must establish reference intervals for each methodology validated within that laboratory in order to create a diagnostic range that can be used medically. A minimum of 100 healthy individuals is sampled. A 95% reference interval is created for normally distributed analytes using the formula, mean +/- 1.96 standard deviations. Therefore, the normal medical reference interval used by clinicians excludes 2.5% of normal individuals at the high and low ends of the range (Fig. 23.2). Biochemical reference intervals for common species of psittacines (parrots), passerines (canaries and finches), and galliformes (turkeys and chickens) have been established by specialized laboratories, eg, California Avian Laboratory, Citrus Heights, CA. Each laboratory analyzing avian samples should develop species-specific and methodology-specific reference intervals. These are still lacking in some university and private laboratories.

Reference intervals generated by a laboratory represent population reference intervals that are broader than the reference interval generated when repeatedly sampling an individual. Some individuals will regularly have concentrations in the low end of the population's range and some individuals will regularly have concentrations in the high end of the population's range. Therefore, an individual may remain within the population reference range even though there are abnormalities in the patient.

In addition to accurate normal reference intervals, the clinician must have knowledge of the sensitivity/specificity and positive/negative predictive value of a test's ability to diagnose diseases specific to that species. Although a great deal is now known regarding avian medicine, research into the diagnostic application, sensitivity, specificity, and positive and negative predictive values of biochemical analytes is still needed.

MEASURES OF THE ACCURACY OF A TEST

Accuracy is how close the test approximates the true value in the body. Precision measures how far from the mean or average of replicate measurements a particular measurement lies (Fig. 23.3). Most laboratory techniques were designed for use in human medicine and are modified for use in birds. Assessment of analytic accuracy and precision of a technique is very important when assessing different mammalian species, not to mention different kingdoms of animals. Any instrument error such as old bulbs, slight variation in machine temperature, variation in reaction time or degraded reagents can cause decreased accuracy and precision.

Sensitivity, specificity and predictive values are the measures of diagnostic accuracy. In medicine, sensitivity is the likelihood that a diseased patient will have a positive test result in a population of individuals with the disease. Sensitivity is a measure of false negative values. To help remember the relationships note that the letter "N" is present in sensitivity and false negative. Specificity is the likelihood that a patient without the disease has a test value that remains within the reference interval in a population of healthy individuals. Specificity is a measure of false positive values. Note that the letter "P" is present in specificity and false positive. The predictive value of a test is determined by its measurement in a population of healthy and sick individuals. A positive test result is measured when the disease is present (positive predictive value) and a negative test result is measured when the disease is not present (negative predictive value). These can be mathematically determined using the formulas in Table 23.2. Tests that are highly sensitive frequently have a low specificity and vice versa. This does

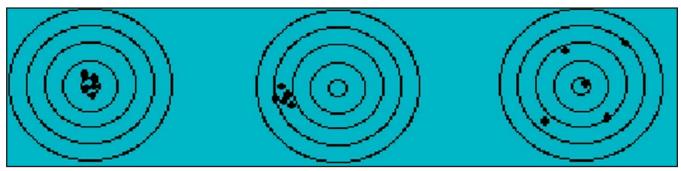

Fig 23.3 | Accuracy vs. Precision. When values are both precise and accurate, they are a tight cluster in the bull's eye. The precise values are all similar, but are some distance from the actual value. The accurate values are all within the third circle, with one almost approximating the actual value, but are scattered around the bull's eye.

Table 23.1 | Statistical Analysis of a Diagnostic Test

Formulas for the calculation of diagnostic sensitivity, diagnostic specificity, positive predictive value and negative predictive value. TP = true positive, TN = true negative, FP = talse positive, FN = talse negative.

- Diagnostic sensitivity = $\frac{TP}{TP+FN}$
- Diagnostic specificity = $\frac{TN}{TN+FP}$
- Positive predictive value = $\frac{TP}{TP+FP}$
- Negative predictive value = $\frac{TN}{TN+FN}$

not mean that the test is worthless. It simply means that it may have to be used with other tests to assess organ function and disease.

Sample Handling

HANDLING

In the USA, many exotic animal practitioners perform venipuncture using a syringe that has been coated with injectable sodium heparin to prevent clot formation. Experienced avian veterinarians working with experienced restrainers, who minimize trauma to the vessel wall, can collect a high-quality sample without the addition of sodium heparin. Reducing the amount of sodium heparin in the sample is desirable. If most of the heparin is expelled, it will minimally affect the sample. However, the amount of heparin actually retained may vary among samples. Any droplets remaining may cause dilutional effects as well as interfere with some analytical tests such as sodium and albumin. Samples for biochemical analysis should be placed into a lithium heparin microtainer rather than a red-topped tube to avoid variable clotting time and gelling of serum. Anticoagulant tubes must be filled to the appropriate volume. A plasma separator also can be used to increase plasma sample volume, though these tubes tend to be slightly more expensive.

Avian plasma samples are frequently yellow due to

carotenoid pigments; rarely, in severe disease states, avian plasma may be truly icteric from bilirubin. 39,49 Pink or red plasma is usually indicative of hemolysis, though dyes from food should be ruled out. Green-tinged plasma is rarely observed, may be caused by biliverdin and is usually indicative of liver failure.23,31 When working with smaller species of birds, tuberculin or insulin syringes are frequently used, however, not all of these syringes have detachable needles. Avian red blood cells are larger and deteriorate more quickly than mammalian erythrocytes. This can make accurate analysis difficult with ideal sample handling. Ejecting blood through a 25-gauge or smaller needle can cause moderate to marked hemolysis that will invalidate many biochemical analysis. 48 To avert this, attached needles can easily be cut from the syringe using a pair of large veterinary nail clippers or scissors before expelling the blood from the syringe.

ANTICOAGULANT

Prior to collection, the appropriate sample container is labeled with the names of the owner, patient and the signalment. Color-coded, rubber stoppered, evacuated tubes are well standardized. Green-topped tubes contain heparin, which should be used for plasma chemistry analysis in birds. Lithium heparin is the recommended anticoagulant, as sodium or potassium heparin can falsely increase the electrolyte values and skew anion gap and acid base analysis. Ammonium heparin should not be used, as it significantly increases ammonia and BUN concentrations. Heparin inhibits coagulation by binding to antithrombin III and greatly accelerates the inhibition of thrombin (factor II) by antithrombin III. Factors VII (proconvertin) and X (Stuart Prower factor) also appear to be inhibited by the heparin-antithrombin III complex.

The disadvantage of heparin is that leukocytes do not stain as well, and platelets and white blood cells clump much more than they do in blood collected in ethylenediaminetetra-acetic acid (EDTA). This leads to decreased accuracy and precision in the complete blood count (CBC) (see Chapter 22, Diagnostic Value of Hematology). Purple or lavender-topped tubes contain EDTA. Bluetopped tubes contain citrate and are used to harvest plasma for coagulation analysis. Both citrate and EDTA prevent coagulation by chelation of calcium (factor IV), an electrolyte essential to coagulation. Neither purplenor blue-topped tubes are recommended for chemistry analysis because chelation of ions interferes with most reactions.

Red-topped tubes lack anticoagulant and are used to harvest serum required in antibody, hormone, and other protein analysis. At least 25% of avian serum samples will form a proteinaceous gel when separated, significantly decreasing sample volume and occasionally completely preventing biochemical analysis. Additionally, time to clot formation in avian species is variable, due in part to greater dependence on the extrinsic coagulation cascade. The use of heparinized plasma therefore decreases variability in time to sample separation and improves the chance of obtaining an adequate sample volume.

HEMOLYSIS

Hemolysis directly interferes with spectrophotometric absorbance readings and alters the pH of enzymatic reactions. Constituents that are found in higher concentrations within erythrocytes than in serum will be increased, eg, aspartate aminotransferase (AST) and, potentially, potassium. Alteration in the enzymatic reactions may appear randomly and cannot be predicted. Hemolysis can and should be monitored visually. Any sample that is more than very light pink should not be used diagnostically. Additionally, if the sample is analyzed by an automated hematology analyzer, a mean cell hemoglobin concentration (MCHC) that is greater than the reference range is an indication of possible hemolysis.

Artifactual change can vary between methods employed. Technical support and literature should be reviewed for each machine. Hemolysis in the sample falsely decreases bile acids measurement by the colorimetric assay, while radioimmunoassay (RIA) is unaffected. For many methods, hemolysis falsely increases alanine aminotransferase (ALT), aspartate aminotransferase (AST), lactate dehydrogenase (LDH), creatinine, calcium, albumin, potassium, amylase, creatine kinase (CK), hemoglobin, and MCHC. A false decrease in triglycerides can occur. Glucose, magnesium, phosphorus, cholesterol, alkaline phosphatase and lipase can be either increased or decreased depending on the methodology.48

LIPEMIA

Lipemia may be present in postprandial samples, but

also may be indicative of underlying disease such as hypothyroidism, diabetes mellitus, hyperadrenocorticism, pancreatitis, or a primary lipid/lipoprotein disorder. Lipemia causes refraction of light and therefore causes error in many spectrophotometric and all refractometric methods (see Fig. 23.1).

Lipid can be partially cleared by ultracentrifugation or precipitating agents (polyethylene glycol, liposol, lipoclear). These techniques and clearing agents may themselves induce artifact. Additionally, the removal of lipid from a sample may in itself induce an artifact in analytes of interest. For example, lipoproteins bind bile acids, which would be discarded along with the lipid following ultracentrifugation. This may be one factor that contributes to the occasional measurement of decreased postprandial values in comparison to fasted values. The scattering of light due to lipemia will falsely increase the postprandial bile acid measurement. Varying technique can therefore significantly alter bile acid values. This underscores the importance of contact with your laboratory to determine which technique is used and that the techniques used are appropriate.

Again, technical support and literature should be reviewed for each machine. Wet chemistry analyzers are generally more impacted by lipemia than dry chemistry analyzers. Electrolytes measured by ion-specific electrodes are not affected by lipemia, but electrolytes measured by flame photometry are decreased.

Lipemia falsely increases all of the liver enzymes, alkaline phosphatase, hemoglobin, MCHC, bile acids, total bilirubin, glucose, calcium and phosphorous. Total protein measured by a refractometer is falsely increased, but the biuret method is minimally affected even by severe lipemia. BUN and gamma glutamyl transferase (GGT) may be increased or decreased depending on the methodology. Albumin is generally decreased using bromcresol green methodology.

Age

In general, non-protein nitrogen concentrations are lower in young, growing animals, as most nitrogen is being consumed by growth. In neonatal eclectus parrots (Eclectus roratus), macaws and cockatoos, albumin, globulin and AST also have been found to be lower than in adults. This is likely due to decreased production of these analytes by the neonatal liver, combined with increased utilization in the tissues that is needed for growth. Additionally, it was found that calcium, sodium and chloride were decreased in chicks in comparison to adults. Alkaline phosphatase, a compound produced in

osteoblasts, is found in higher concentrations in growing animals. Blood phosphorus and potassium also are found in increased concentrations in young birds due partially to increased concentration of growth hormone, and mobilization for muscle and bone growth.^{11,12,13}

Analytes

The following descriptions of analytes contain method, physiology and diagnostic value sections. The method sections are designed for practitioners who are running some values in their practice and, therefore, need to be familiar with the method that they are using to analyze plasma biochemical values. Different methods frequently will produce different results. The International Federation of Clinical Chemists (IFCC) has standardized some test methods and these should be used. Analyzer manufacturers may sell alternate methods at reduced prices to veterinarians, with the knowledge that they do not meet current standards. The veterinarian should be aware of the appropriate method to use and the limitations of interpretation in a species. Some artifacts and drug interactions are discussed in the method sections, though these should not be considered to be complete listings of those interactions. Product specification sheets for the methodology as well as technical support should be used as necessary. The sections on physiology discuss the function of the analyte in the body. The sections on diagnostic value discuss clinical utility in birds. See also the Differential Diagnoses in Table 23.2.

Acetoacetate, Acetone (Ketones)

Method

Common urine test strips present in most practices use the Rothera test in which alkaline nitroprusside turns purple in the presence of acetoacetate and, to a lesser extent, acetone. A third, relatively acutely produced ketone, 3-hydroxybutyrate, is not measured by this reaction. False negatives may occur if the patient is producing only 3-hydroxybutyrate. If diabetes is suspected and ketones are not measured, the urine should be rechecked in 48 hours. Some drug interactions may produce false positives, including penicillamine, levodopa and phenylketones.

Physiology

Decreased glucose availability to the tissues results in increased lipase activity in adipose tissue that catalyzes long-chain fatty acids. These are catabolyzed to acetyl CoA that is metabolized to the ketones: 3-hydroxybutyrate, acetoacetate and acetone. These compounds are excreted in urine and can be qualitatively measured in stressful physiologic or pathologic disease states.

Diagnostic Value

Healthy birds do not have ketones in their urine unless they have undergone strenuous activity, eg, migration. Measurement of ketone bodies in the urine is indicative of diabetes mellitus in most birds.

Albumin

Method

Most veterinary laboratories measure albumin using the dye bromcresol green (bcg), which has not been validated in companion avian species. Bromcresol green non-specifically binds protein. Binding of bcg causes increased color in the sample, which correlates with a higher reported albumin concentration. It has been demonstrated in dogs and humans that heparin can cause false increases in albumin concentration due to binding of fibrinogen.59 Avian albumin is markedly different in structure than mammalian albumin and binds bcg with decreased affinity. Comparison of gel electrophoresis and bcg have revealed that bcg results in lower concentrations reported than actually exist in the patient.58 This error is caused in part by use of human albumin standards and controls, which have different binding affinity for the dye than does avian albumin. This error in measurement may result in serious errors when assessing hypoproteinemic syndromes such as liver failure, protein-losing nephropathy and protein-losing enteropathy. At this time gel electrophoresis is the recommended method of albumin determination in avian species. 15,40,60 Bromcresol purple (bcp) also is commonly used in human laboratories and has different protein binding affinity for albumin.^{2,5,64} Bromcresol purple may result in more accurate avian albumin measurement and better diagnostic acuity. Further study is needed.

Physiology

Albumin, a small, approximately 65-kD protein, is the most abundant protein found in plasma, most extravascular body fluid, CSF and urine. Albumin's synthesis by the liver is primarily controlled by plasma oncotic pressure. Albumin's main function is the maintenance of colloid oncotic pressure in the intravascular and extravascular spaces. Albumin also functions as a carrier protein to transport a large number of compounds including calcium and administered drugs. Albumin levels are lower in chicks than in adults.

Diagnostic Value

Accurate assessment of albumin enables the practitioner to assess hypoproteinemic disease such as liver failure, protein-losing nephropathy and protein-losing enteropathy. This diagnosis may lead to alternate fluid therapy such as colloid (hetastarch) administration to prevent edema, which is rarely seen in birds, and ascites. A true increase in albumin is pathognomonic for dehydration

 $\textbf{Table 23.2} \ | \ \textbf{Differential Diagnoses Based on Chemistry Abnormalities*}$

Albumin Increased	Dehydration - generally accompanied by increased globulin and total protein Reproductive - mild increase observed in females during egg formation	
Albumin Decreased	Liver failure Cirrhosis/fibrosis Neoplasia Portosystemic shunt Amyloidosis Renal loss Glomerulonephritis/sclerosis Intestinal Malabsorption/maldigestion Mycobacterial disease Endoparasites Malnutrition (severe) Exudative skin disease Burns Large wounds Vasculitis Frostbite External blood loss (subacute to chronic) Inflammatory disease state (seen with increased globulins) Septicemia Viremia Neonates - normally lower than adults	
Alkaline Phosphatase Increased	Bone isoenzyme Trauma Growth Osteosarcoma Osteomyelitis No hepatic-associated increase currently documented	
Ammonia Increased	 Hepatic disease/failure Cirrhosis Neoplasia Polyoma Artifactual Hemolysis 	
Amylase Increased	Pancreatic Inflammation/Infection Neoplasia Necrosis Pancreatic duct obstruction (eg, egg binding) Zinc toxicity Enteritis Renal disease (decreased filtration) (mild to moderate increase)	
Anion Gap Increased	Respiratory acidosis Anoxia (anesthetic induced, other) Respiratory disease (chlamydia, aspergillosis, etc) Hyperglobulinemia (reproductive, inflammatory) Metabolic acidosis (increased lactic acid and other unmeasured anions) Renal failure Gastrointestinal bicarbonate loss Hypoperfusion/reperfusion Shock Diabetic ketoacidosis Toxic Ethylene glycol (mammals)	
Aspartate Aminotransferase (AST) Increased	Muscle damage Seizures Trauma Capture myopathy (exertional rhabdomyolysis) Intramuscular injection Hepatic damage Drugs (cephalosporins, metronidazole, trimethoprim sulfa, dexamethasone) Hemochromatosis (iron storage disease) Endocrine disease (diabetes mellitus, hyperthyroidism) Hypoxia (cardiopulmonary in origin) Lipidosis (severe)	

alifies*		
Aspartate Aminotransferase (AST) (cont.) Increased	Hepatic damage (continued) Infection [(bacterial, mycobacteriosis, chlamydophilosis, polyoma virus, Pacheco's disease - herpes virus, adenovirus, reovirus, duc virus hepatitis, Plasmodium, Trichomonas, Histomonas (turkeys), Leucocytozoon (ducks and geese), Atoxoplasma] Toxic [(aflatoxin/mycotoxin, cottonseed (Gossypium sp.), Crotalaria sp., oleander (Nerium sp.), rapeseed (Brassica napus), ragwort (Senecio jacobea), castor bean (Ricinus communis)] Neoplasia Primary Secondary Artifactual Erythrocyte leakage	
Bicarbonate (CO ₂) Increased	Compensated respiratory acidosis Respiratory disease Drugs (anesthetics) Small bowel obstruction Gastric vomiting Obstruction Lead poisoning	
Bicarbonate (CO ₂) Decreased	Metabolic acidosis Dehydration Renal failure Respiratory alkalosis Tachypnea/panting Excess anesthetic ventilation Artifactual Delayed analysis

Glucose Decreased	Liver failure Starvation in small birds Neoplasia Septicemia		
Iron Increased	Hemochromatosis Inflammation Artifactual Hemolysis		
Iron Decreased	Chronic blood loss Nutritional dietary deficiency* *Ed. Note: Unlikely on formulated diet, but possible on a seed/fruit.		

Lipase Increased	Enteritis Pancreatitis Pancreatic neoplasia Renal disease (decreased loss)
Phosphorus Increased	Renal disease Neonates Reproductive Egg formation (concurrent rise in calcium) Nutritional Hypervitaminosis D Increase dietary phosphorus Toxic Jasmine ingestion Neoplasia Osteosarcoma Inflammation Osteomyelitis Artifactual hemolysis/delayed serum separation Primary hyperparathyroidism Nutritional secondary hyperparathyroidism Neoplasia: PTH-like hormone
Phosphorus Decreased	Diabetic ketoacidosis Dietary deficiency
Potassium Increased	Renal failure Diabetic ketoacidosis Severe muscle/tissue damage Dehydration Drugs - ACE inhibitors - Potassium-sparing diuretics Artifactual - Collection in potassium heparin
Potassium Decreased	Alkalosis Drugs Penicillins Amphotericin B Loop diuretics Insulin therapy Gastrointestinal loss Renal disease (chronic)
Sodium Increased	Gastric vomiting (water loss) Intestinal fluid loss Renal failure Dehydration
Sodium Decreased	Diabetes mellitus Gastric vomiting Intestinal sodium loss Endoparasitism Burns Chronic effusions Egg yolk Psychogenic polydipsia Renal failure (chronic) Artifactual Hyperlipidemia
Total Protein Increased	Dehydration (albumin and globulin) Artifactual Hemolysis
Total Protein Decreased	Hemorrhage (chronic) Intestinal loss Liver failure Renal loss Immune suppression
Uric Acid Increased	Renal disease Postprandial (carnivores) Dehydration (severe)
Uric Acid Decreased	Liver failure Starvation

and would indicate the need for administration of IV crystalloid fluids.

Alkaline Phosphatase (ALP)

Method

Numerous methods have been developed to determine ALP activity. The IFCC recommended method uses 4nitrophenyl phosphate (4-NPP) and 2A2M1P as a phosphate acceptor buffer at 37° C and absorbance at 405 nm. ALP catalyzes the hydrolysis of 4-NPP, forming phosphate and free 4-nitrophenol (4-NP) in an acidic solution. Alkalinization causes conversion of colorless 4-NP to 4-nitrophenoxide ion, which is an intense yellow color. As veterinary laboratories may employ different methods, normal reference intervals may be markedly different. Caution should be used when assessing a patient using reference intervals from a textbook. Laboratory-specific reference intervals should be gener-

Physiology

Alkaline phosphatase is a glycoprotein dimer with subunit masses ranging from 40 to 83 kD. The protein's exact function is unknown. Mammalian and avian isozymes of alkaline phosphatase have been identified in cell membranes in the liver (biliary epithelium), kidney, intestine, bone (osteoblasts), as well as a steroidinduced form in dogs. Isoenzymes from osteoblasts, duodenum and kidney have predominated in studies involving pigeons and domestic fowl. 28,43,45 Very low levels of alkaline phosphatase have been identified in the liver of pigeons and psittacines. Alkaline phosphatase levels are higher in chicks than in adults.

Diagnostic Value

In mammals, alkaline phosphatase is of particular interest in two specific disease states: biliary disease frequently associated with cholestasis and bone disease associated with increased osteoblastic activity. ALP does not increase with simple hepatocellular damage. In avian species at this time, marked increases in ALP have been associated only with increased osteoblastic activity including traumatic, neoplastic and infectious disease states. Further investigation into specific cholestatic and biliary disease such as biliary carcinoma is warranted to assess the sensitivity and specificity of ALP in these biliary diseases.

Ammonia

Method

Both enzymatic and chemical methods are used to measure ammonia. Enzymatic assay with glutamate dehydrogenase is the most frequently used method.⁵² Glutamate dehydrogenase catalyzes the conversion of ammonium ion and 2-oxoglutarate to glutamate and water. This

reaction oxidizes Nicoti Adenine Dinuleotide Hydrogen (NADH) to Nicotinamide Adenine Dinucleotide (NAD), which can be optically measured at 340 nm.

Meticulous precautions must be taken in sample handling to prevent false increases in ammonia concentration. Samples must be drawn cleanly, using an evacuated tube, and processed immediately for accurate results. Poor venipuncture technique or increased exposure to air may result in increased ammonia levels. Probing for a vein causes tissue damage that may elevate ammonia levels. Drawing blood into a syringe and transfer of that blood to a microtainer, or partial filling of an evacuated tube allows subsequent entry of air that may cause elevation of ammonia levels. Serum samples and ammonium heparin may cause falsely elevated levels. Production of ammonia by deamination of amino acids in the blood will occur once the specimen has been drawn. At 0° C, delays exceeding 15 minutes between blood sampling and centrifugation can increase ammonia concentrations.

Ammonia analysis are available on many dry chemistry analyzers used in practice. Machines-specific reference ranges should be established, as different methodologies will produce different reference intervals.

Physiology

The major source of ammonia is the gastrointestinal tract. It is derived from the hydrolysis of glutamine in the small and large intestine and from the action of bacterial proteases, ureases, and amine oxidases on digested food in the colon. Ammonia is converted to the less toxic uric acid and urea in the liver.

Diagnostic Value

Though plasma ammonia has not been validated in healthy or ill birds, some clinicians have observed up to a fourfold increase in blood ammonia values in birds with liver failure.

Amylase

Method

The three broad classifications of alpha-amylase (endoamylase) assays are saccharogenic, amyloclastic and chromogenic digestion of starch to glucose or maltose. The most commonly used assay in veterinary laboratories is the chromogenic alpha-amylase assay, which is the most appropriate assay in the canine.35 This assay detects the release of dyes bound to synthetic starch substrates that are released as the starch is digested by amylase.

Physiology

Alpha-amylases are calcium-dependent metalloenzymes that catalyze hydrolysis of complex carbohydrates at

internal binding sites. The predominant sites of production are the pancreas and the duodenum. Trypsin in the small intestine degrades the enzyme, though some amylase frequently is still detectable in the feces. Urinary clearance of this small, 55- to 60-kD protein also has been documented in mammals.

Diagnostic Value

Urine-to-serum ratios are used in human medicine to diagnose acute pancreatitis.²⁶ Though this assay is frequently used for the diagnosis of pancreatitis in humans, it has decreased specificity and sensitivity in the dog. Validation of this assay for diagnosis of pancreatitis in birds is needed.

Anion Gap

Method

This number is calculated from the following formula:

Cations - Anions or (Sodium + Potassium) - (Chloride + Bicarbonate)

Physiology

The gap is generally around 15 mEq/L (mmol/L) in most species with some variation, and represents unmeasured anions such as phosphate, sulfate, lactate, ketones, and drugs such as salicylates and ethylene glycol metabolites. If bicarbonate is not available, the total carbon dioxide value can be substituted. Generally, an increased anion gap indicates acidosis.

Diagnostic Value

Anion gap facilitates assessment of metabolic and respiratory acidosis. An increased anion gap should incite a search for the cause of increased numbers of unmeasured anions.

Acidemia causes an extracellular potassium shift as hydrogen ions enter the cells; the more chronic the disorder, the greater the intracellular potassium depletion. When correcting the acidosis, potassium moves back into the cell creating a potentially life-threatening hypokalemia. Accurate assessment of the acid base status of patients with chronic respiratory disease is essential to provide appropriate fluid therapy and electrolyte replacement.

Aspartate Aminotransferase (AST)

Method

The IFCC has standardized this reaction to some extent by limiting it to the rate-limiting reaction of L-aspartate and 2-oxoglutarate catalyzed by AST to form oxaloacetate and L-glutamate. Oxaloacetate is then reacted with NADH in the presence of malate dehydrogenase to form L-malate and NAD. Pyridoxal-5'-phosphate is a required coenzyme in the reaction and the IFCC recommends

addition of this coenzyme in the reaction. The conversion of NADH to NAD can be optically measured at 340 nm. Reference intervals may vary slightly with variation of reagent concentration. AST is present in the cytosol of erythrocytes and extended red cell exposure can cause increased plasma AST concentration.

Physiology

The aminotransferases, including AST (formerly glutamate oxaloacetate transaminases, GOT) and alanine aminotransferase (ALT) (formerly glutamate pyruvate transaminases, GPT), are a group of enzymes that catalyze the interconversion of amino acids by transfer of amino groups. A variety of tissues, predominately liver and muscle, contain high aspartate aminotransferase. The mitochondrial and cytosolic isoenzymes of AST are approximately 90 kD in size.

Diagnostic Value

AST is not specific for hepatocellular damage, but is highly sensitive in detecting hepatocellular damage caused by ethylene glycol in pigeons. ⁴⁰ Plasma AST activity returned to normal within 100 hours after doxycycline-induced muscle trauma in pigeons. AST activity is currently considered to be a very sensitive but nonspecific indicator of hepatocellular disease in other avian species as well, and is used with the muscle-specific enzyme creatine kinase (CK) to differentiate between liver and muscle damage. ^{16,30} ALT also is not liver-specific in birds. Prolonged postinjection increases in ALT decrease the diagnostic utility of this enzyme in the diagnosis of liver disease. ALT is therefore frequently omitted from avian chemistry panels.

Bicarbonate

Method

A common reaction used to measure bicarbonate is based upon phosphoenolpyruvate carboxylase (PEPC) utilizing bicarbonate present in the sample to produce oxaloacetate and phosphate. Malate dehydrogenase then catalyzes the reduction of oxaloacetate to malate, and the oxidation of NADH to NAD. NADH oxidation can be measured optically at 340 nm. Extended exposure of the sample to air (under-filled vials), late separation from the cell fraction or a dehydrated sample can introduce significant error in this measurement.

Physiology

Approximately 90% of carbon dioxide present in serum is in the form of bicarbonate. Therefore, measurement of total CO_2 is frequently used in place of bicarbonate measurement. This is different than pCO_2 , which represents the remaining small percentage actually present in the gaseous form. The combination of water and CO_2 forms the weak acid carbonate, $\mathrm{H_2CO}_3$, and its dissociated

Table 23.3 | Acid Base Imbalances and the Body's Compensation

	[H+]	рΗ	Imbalance	Compensation
Respiratory acidosis	1	↓	↑ pCO ₂	↑ [HCO ₃ -]
Metabolic acidosis	1	↓	↓ [HCO₃-]	↓ pCO ₂
Respiratory alkalosis	↓	1	↓ pCO ₂	↓ [HCO₃·]
Metabolic alkalosis	↓	1	↑ [HCO ₃ -]	↑ pCO ₂

forms, bicarbonate and hydronium ion, comprise one of the main buffering systems in animals. The Henderson Hasselbach equation, pH = $6.1 + \log (HCO_3 - / H_2CO_3)$ where 6.1 = pK for the HCO_3 -/ H_2CO_3 buffer pair, is used to quantitatively analyze buffering by carbonic acid.

Diagnostic Value

The measurement of bicarbonate, usually in conjunction with sodium, potassium and chloride, is used in the assessment of acid-base balance resulting from metabolic or respiratory disease. Respiratory acidemia is a common sequela in birds that have respiratory compromise or are anesthetized. Unfortunately, it is currently rarely assessed or treated. See the Anion Gap section for information and Table 23.3 for summaries of acid base assessment.

Bile Acids (BA)

Method

Radioimmunoassay (RIA) and enzymatic assay are the two commonly used methods for bile acid determination. Liquid chromatography also can be used in research settings. RIAs measure non-sulfated, conjugated bile acids.29 Though less affected by hemolysis, RIA, an antibody-based assay, will measure only an unspecified proportion of bile acids in different species. The enzymatic BA method, validated for canine, feline and human samples, measures the 3-alpha-hydroxyl group present in most BAs. This test would be expected to best approximate total BA concentration in most avian species. The value generated by RIA is generally lower than the enzymatic measurement.

The pre- and postprandial sampling used in dogs and cats would likely be ideal for birds as well. However, the crop has varying emptying times in different species, and crop stasis is common in sick birds such that standardization of postprandial sampling is impossible. If possible, a fasted sample is preferred to eliminate random postprandial increases in BA concentration. Fasting is not necessary in species that do not have a gall bladder, such as pigeons, ostriches, and most parrots.⁴⁸

Physiology

Bile acids are a group of amphipathic salts that act as detergent molecules both to facilitate hepatic excretion of cholesterol and to solubilize lipids for intestinal

absorption. They promote formation of polymolecular aggregates known as micelles, which contain hydrophobic lipid in the center and have a hydrophilic outer surface. Bile acids are absorbed in the distal small intestine into the plasma and recycled from the blood by hepatocytes (enterohepatic circulation).

Diagnostic Value

Bile acids are used to assess liver function. 29,30,43 The clinician should be aware that RIA methodologies will generally produce significantly lower numbers than enzymatic methods. Laboratories should be questioned to determine which methodology they are using. Generally, using the enzymatic method, $>75 \mu mol/L$ suggests hepatic insufficiency while >100 μ mol/L is diagnostic for decreased liver function. Amazon parrots normally have slightly higher BA concentration than do other companion avian species.29 Decreased bile acids may occur as a result of compromised intestinal absorption.

Bilirubin/Biliverdin

Method

The most commonly used method for bilirubin measurement are based on the diazo reaction, first developed by Ehrlich in 1883. Diazotized sulfanilic acid (diazo reagent) reacts with bilirubin to produce two azodipyrroles, which are reddish purple at neutral pH and blue at low or high pH values. The fraction of bilirubin that reacts with sulfanilic acid in the absence of alcohol is direct bilirubin (conjugated). Total bilirubin is determined after the addition of alcohol, and indirect bilirubin (unconjugated) is determined by subtracting direct bilirubin from total bilirubin.

At this time, biliverdin is measured only by high performance liquid chromatography (HPLC) for both clinical and research purposes.

Physiology

Bilirubin is the metabolic breakdown product of heme derived primarily from senescent erythrocytes. There are three types of bilirubin: unconjugated, conjugated and a fraction irreversibly bound to protein. The unconjugated portion of bilirubin is the most clinically important fraction, as this is most likely to cause tissue damage. Birds have heme oxygenase, which converts the protoporphyrin in heme to biliverdin;4 however, birds and reptiles have significantly decreased hepatic production of biliverdin reductase that converts biliverdin to bilirubin. Bacteria in the intestine may produce biliverdin reductase and bilirubin may be absorbed from the GI tract. Additionally, though significantly decreased, hepatic biliverdin reductase is still present in some birds. 49,61 Bilirubin and biliverdin are detoxified via the glucuronic acid pathway in the liver and excreted in bile.

Diagnostic Value

Cholestasis and liver failure generally result in increased concentrations of biliverdin in birds. Bilirubin has been previously dismissed as unhelpful in the diagnosis of liver disease. However, there are reports of increased bilirubin in severe disease states.⁴⁹ Diagnostic sensitivity and specificity should be further assessed.

Blood Urea Nitrogen (BUN)

Method

There are numerous enzymatic, chemical and electrochemical methods for measurement of urea with good specificity for the compound. Reference intervals will vary with the methodology used. BUN levels are normally low in birds and may be below the detectable limit of some (but not all) assays used in the laboratory.

Physiology

During protein catabolism, nitrogen in amino acids is converted to urea in the liver by the action of the urea cycle enzymes. Though birds are predominately uricotelic, with urea being a minor component of nitrogen excretion, many still have functional hepatic enzyme action to drive the urea cycle. Additionally, bacteria in the gut may produce urea as well as ammonia, which can be absorbed from the intestinal lumen. The majority of urea is excreted through the kidneys, with some excreted through the GI tract in bile and through the skin. Urea is highly diffusible and, in addition to initial glomerular filtration, it moves passively through the renal tubules.

Diagnostic Value

Prerenal azotemia may be observed in dehydrated birds. 36,37 In penguins, it appears that BUN is not elevated postprandially, as was uric acid. 34 On the other hand, peregrine falcons (*Falco peregrinus*) had elevated BUN and uric acid when sampled 8 hours postprandially. 44 Renal disease also has been shown to cause azotemia. 40 BUN and uric acid may be used together — as separate pieces of the puzzle with history, physical exam, urinalysis and other more invasive diagnostic tests — to adequately assess prerenal versus renal disease. Using decreased BUN concentration as an indicator of liver failure has not been assessed in avian species, but may be possible in some species such as cockatoos.

Calcium (Ionized/Free)

Method

Ion-selective analyzers^b capable of providing immediate whole-blood determinations of free calcium, electrolytes and blood gases are widely available. Calibration solutions, samples and wash solutions are pumped through a measuring cell containing calcium ion-selective, refer-

ence and pH electrodes. Sensitive potentiometers measure the voltage differential between electrodes, while the microprocessor calibrates the system and calculates calcium concentration and pH. Most of these units function at 37° C and so any significant temperature differential will make them inaccurate. These units must be maintained with regular calibration and assessment of controls.

Physiology

The ionized or free fraction of calcium is the freely diffusible, biologically active fraction. It is generally very tightly regulated by all species. It has been shown to increase mildly during active reproductive cycles in oviparous species.³³ Regulation of plasma calcium is achieved by interactions of parathyroid hormone, active vitamin D and calcitonin.

Diagnostic Value

A general reference interval is 1.0 to 1.3 mmol/L used in avian species at University of California Davis. Free calcium concentration in normal laying hens was found to be 1.3 to 1.6 mmol/L.³³ Species-specific values should be generated within the laboratory. There has been little work currently published on ionized calcium in disease in birds, but it will likely aid in differentiation of pathologic states such as renal disease, egg binding and malnutrition. Low ionized calcium in a symptomatic, possibly seizuring animal is an indication for well-monitored, intravenous calcium administration (see Chapter 5, Calcium Metabolism).

Calcium (Total)

Method

Photometric measurement of total calcium is generally used in veterinary diagnostic laboratories, though atomic absorption methods also may be used in research facilities. The two most common dyes used to bind calcium are o-cresolphthalein complexone (CPC) and arsenazo III. The sample is acidified to release protein-bound and complexed calcium. In alkaline buffered solution, CPC forms a red chromatophore when bound to calcium that can be measured at 580 nm. High magnesium concentration, lipemia and hemolysis will increase and invalidate results.

Physiology

The vast majority of calcium is stored in the skeleton as hydroxyapatite. In blood, a large portion of calcium is free, generally a smaller portion is protein bound and the smallest fraction is complexed to anions. Oviparous species have remarkable variability of the protein-bound and complexed portions due to estrogen-induced transport of calcium-bound yolk proteins to the ovary.⁵⁶

Diagnostic Value

Calcium concentrations are dependent on the reproductive cycle, sex and possibly season; separate reference intervals for each of these variables should be established for accurate clinical evaluation of calcium values.

Absorption, excretion and compartmentalization all affect increases and decreases in plasma calcium. Disease states affecting the reproductive, renal, and digestive tract, as well as severe nutritive disorders may change calcium concentration.

The relationship between plasma total calcium concentration and total protein and albumin concentrations has been evaluated in several bird species. 3,38,46,62 Though correlations between calcium, total protein and albumin have been found in some species, they differ markedly between species. There are significant species differences in protein-calcium correlations such that generalized adjustment formulae will not be helpful in a clinical setting where many different species are evaluated. Total plasma calcium concentration, even if corrected for the effects of protein binding, does not provide information regarding ionized calcium concentration, the physiologically active fraction.

In oviparous species, increased phosphorus and calcium concentrations are observed during egg formation in females. Generally, these occur together and the calcium:phosphorus ratio stays above one in healthy individuals. If the calcium:phosphorus ratio is below one, renal disease should be investigated.

Chloride - See Electrolytes

Cholesterol

Method

There are numerous methods for lipid and cholesterol determination, with significant laboratory variation. Enzymatic methods are most commonly used in veterinary laboratories. Generally, cholesterol ester is reacted with water in the presence of cholesteryl ester hydrolase to form whole cholesterol and fatty acid. Cholesterol then reacts with oxygen in the presence of cholesterol oxidase to form cholest-4-en-3-one and hydrogen peroxide. Hydrogen peroxide is then measured in a peroxidase-catalyzed reaction that forms a dye that can be measured at approximately 500 nm.

Physiology

This 27-carbon, steroid alcohol is found in some concentration in almost all cells and body fluids in animals, and at a much lower concentration as phytosterols in plants. There is no cholesterol in plants. Cholesterol enters the intestine from three sources, the diet, bile and intestinal secretions, and sloughed cells. Cholesterol is metabolized by pancreatic secretions, intestinal secretions, and bile to micelles and then to chylomicrons that are absorbed into lacteals across intestinal villi. Transport of cholesterol in blood occurs via lipoproteins as high-density, intermediate-density, low-density, and very low-density lipoproteins. Higher density lipoproteins have increased concentrations of cholesterol. Cholesterol is synthesized and degraded in the liver (see Chapter 4, Nutritional Considerations, Section II Nutritional Disorders).

Diagnostic Value

Cholesterol levels may be altered in a normal bird due to oviparity, as well as postprandially. It should be noted that cholesterol can be elevated in oviparous reproductively active females before eggs can be visualized on a radiograph and may be accompanied by hyperostosis. In captive psitticines, cystic ovarian disease is a common syndrome that presents with the above mentioned clinical and laboratory findings in the absence of egg-laying (see Chapter 18, Evaluating and Treating The Reproductive System). When separated by plasma gel electrophoresis, the lipoproteins that transport cholesterol migrate predominately to the alpha and beta globulin regions. Cholesterol levels are rarely diagnostic but may be useful in determination of various disease syndromes (Table 23.3). HDL and LDL cholesterols are being investigated. Preliminary studies in birds show similar trends as those seen in humans (Stanford, 2004).

Creatine Kinase (CK)

Method

Bioluminescent methods are most sensitive and use the reaction of ATP (adenine triphosphate) with luciferin/ luciferase. Spectrophotometric methods are used most commonly in veterinary laboratories, ATP also is used as the rate-limiting component of the reaction. CK catalyzes the reaction between creatine phosphate and ADP (adenine diphosphate) to form creatine and ATP at a pH of 6.7 and the reverse reaction at a pH of 9. This is coupled to a hexokinase-catalyzed reaction to form NADPH (reduced form of NADP). This conversion of NADP (nicotinamide adenine dinucleotide phosphate) to NADPH can be measured at 340 nm. Excess magnesium, manganese, calcium, zinc, copper, citrate, nitrate, iodide, bromide, malonate and L-thyroxine are inhibitory to the reaction and result in decreased values.

The addition of adenosine-5-monophosphate (AMP), N acetylcysteine, EDTA and diadenosine pentaphosphate (Ap5A) has been advocated to decrease changes in accuracy due to the above compounds. Addition of these components will change the value reported and result in significant laboratory variation.

Physiology

CK is a magnesium-dependent dimeric enzyme that catalyzes the reaction of ADP and creatine phosphate (CrP) to ATP and creatine in skeletal, cardiac and smooth muscle, as well as brain. It is present in the cytosol and mitochondria of myocytes.

Diagnostic Value

CK is increased for a short, <72-hour time period following myocyte damage or necrosis in birds.⁴⁷ Consideration should be given to the fact that all muscular structures in the body may be involved in CK elevation, including skeletal muscle, cardiac muscle and, less likely, muscle of the gastrointestinal tract. In mammalian species, hypothyroid patients frequently have marked (three- to five fold) increase in CK. This has not been reported in avian species at this time, but may exist.

Electrolytes - Chloride, Potassium, Sodium

Methods

The most common method for measuring electrolytes in veterinary laboratories is the ion-specific electrode (ISE). An ion-specific membrane is reacted either directly with plasma and serum or indirectly with a large volume of diluent, and then exposed to the membrane. The potentiometer measures the change in electromotive force (charge) in comparison to a reference electrode. The microprocessor then compares the unknown sample to a standard curve created from calibrators.

This method is very different from the spectrophotometric methods generally used in smaller machines in practitioner's offices. In this reaction, a specific ionophore changes color upon binding to the electrolyte. These dyes are measured by a spectrophotometer. Actual values that are generated by the two methods may be dramatically different and result in some difference between in-house and laboratory-generated reference intervals.

ISE is less affected by hemolysis; however, hemolysis will result in significant differences in potassium concentration (generally increased in most species) due to release from intracellular erythrocyte stores.

Physiology

Water homeostasis in any organism is a fundamental dynamic function. The four major electrolytes' primary functions are: maintenance of osmotic pressure, electroneutrality and water distribution. In addition to the main negatively charged ions (anions), bicarbonate and chloride, that are used to calculate anion gap, phosphates, sulfates, lactate, trace elements and proteins, all contribute to electrical neutrality and partitioning of water. The positively charged ions (cations) are predominately sodium and potassium, with contribution from divalent ions such as calcium and magnesium. The bal-

ance of cations and anions maintains pH and regulates nervous, cardiac and muscular function. Anions and cations also are essential cofactors in numerous enzymatic reactions.

Diagnostic Value

Any disease that disturbs water homeostasis will disturb electrolyte distribution and, therefore, plasma concentration. The success of electrolyte replacement therapy, fluid therapy or any attempt to restore nervous, muscular or cardiac function is completely dependent upon accurate assessment of electrolyte abnormalities.

Fibrinogen

Method

Heat precipitation is the most common method used in private practice settings and also is used commonly in commercial laboratories. It is the least accurate method for measuring fibrinogen in mammals, and is generally considered an estimate and not a true measurement. It is likely more inaccurate in birds. Protein is measured by refractometer in non-heated plasma and compared to a protein measurement in plasma heated to 57° C for 3 minutes. The difference in plasma protein represents the precipitated fibrinogen. This is obviously not specific to fibrinogen, as any refractile compound that precipitates will cause error. Birds, in comparison to mammals, frequently have increased quantities of refractile compounds, such as glucose and lipid, which will increase the error of this method.

In veterinary diagnostic labs, a modification of the thrombin test is used to more accurately measure fibrinogen. A known, relatively dilute concentration of thrombin is mixed with fibrinogen. Thrombin enzymatically cleaves fibrinogen to form fibrin, the final step in the coagulation cascade. The fibrin formation rate is proportional to fibrinogen concentration and can be calculated from tables. The tables were derived in humans, and though they work well in small animals, they markedly underestimate fibrinogen concentration in horses. The modified thrombin test has not been validated in avian species.

Physiology

Fibrinogen (coagulation factor I) is an acute-phase protein, made by the liver, that is digested by thrombin to form fibrin. Fibrin, when crosslinked, forms the backbone of the platelet clot.

Diagnostic Value

Fibrinogen is generally increased in non-specific inflammatory states. Fibrinogen concentration was increased above the reference interval in 77% of 89 birds, representing 20 species, with confirmed bacterial disease.²⁴ Decreased fibrinogen may be indicative of end-stage liver failure, but is most commonly detected in mammals with

disseminated intravascular coagulation (DIC). DIC is not commonly evaluated in birds at this time. Further investigation is warranted.

Galactose Clearance (GEC)

Method

Methods to determine GEC and blood galactose concentration in cockatoos have been described.30 The birds were administered 0.5 g/kg of sterile galactose intravenously. Single-point galactose concentrations were best correlated with galactose clearance when sampled at 80 minutes postadministration. Blood samples were deproteinized within 90 minutes of collection by the addition of 1 ml of 0.3 M perchloric acid to a 0.2 ml aliquot of blood. After centrifugation at 1500 g, the clear supernatant was stored at -20° C for preservation until galactose was measured using a commercial ultraviolet method coenzyme assay kitc. Galactose clearance was calculated using the formula GEC (g/min) = $(M-U)(t_{c=0})$ +7) where M is the amount of galactose injected, U is the amount of galactose excreted in urine, and $t_{c=0}$ is the extrapolated time when concentration equals zero. A standard value of 6% urinary excretion was used throughout, as the author determined previously in cockatoos. At 80 minutes, the normal reference intervals were 0.05 to 0.55 g/L for single-point galactose concentration and 0.86 to 1.52 g/min galactose clearance.

Physiology

Galactose is a monosaccharide isomer of glucose that is converted to glucose in the liver through gluconeogenesis pathways for use as energy. Approximately 90% of circulating galactose is filtered from the blood by a healthy mammalian liver during the first pass effect. As hepatic function decreases, the portion of galactose filtered decreases and so the concentration of galactose measured would increase in disease states.

Diagnostic Value

Galactose clearance and galactose single-point concentrations were evaluated during a prospective study on the effects of partial hepatectomy in cockatoos.³⁰ In the study, galactose clearance appeared to be a more sensitive indicator of hepatic insufficiency than plasma enzyme activities or BA levels, and were able to detect an 18% loss of hepatic mass. Though single-point concentration was never increased in animals with 18% hepatectomy, it is likely that this value would increase with more significant liver dysfunction. The authors concluded that GEC has the potential to be a simple, sensitive method of screening birds for decreased hepatic function.

Gamma Glutamyltransferase (GGT)

Method

The IFCC reference method uses L-gamma-glutamyl-3

carboxy-4-nitroanilide as the glutamyl donor and glycyl-glycine as the acceptor in a solution of hydrochloric acid. The nitrobenozoate produced is measured at 410 nm. Other methods are still in use and may produce different values, therefore reference intervals may vary from those values stated in available texts. Lipemia may increase or decrease GGT, depending on methodology used.

Physiology

GGT catalyzes the transfer of the gamma glutamyl group from a donor peptide to an acceptor compound. It is present in serum and in low levels in the cell membrane of all cells except muscle in mammals. It may be involved in glutathione metabolism and detoxification. The primary source of plasma GGT is the biliary system, while significant levels of GGT of renal epithelium origin are found in the urine.

Diagnostic Value

Significant increases in GGT are due to obstruction of or damage to the biliary tree including neoplasia, inflammation or cholelithiasis (stones). Hepatocyte damage alone will not significantly change plasma GGT concentration. In mammals, GGT is a more sensitive indicator of biliary damage than alkaline phosphatase. GGT has previously been thought to be insensitive in the diagnosis of "liver disease," which is likely due to the fact that it will not become elevated in cases where the biliary tree is not compromised. Increased plasma GGT activity was found in the majority of pigeons with experimentally induced liver disease.⁴⁷ Marked increases in GGT activity in birds with bile duct carcinoma also have been reported.⁵⁴

Although reference intervals have not been established, GGT values of 0 to 10 U/L are considered normal at the Schubot Exotic Bird Health Center (College Station, Texas, USA). GGT values appear slightly higher in older Amazon parrots, which may have GGT values up to 16 U/L without other evidence of liver disease. These GGT values are higher than the reported reference intervals for GGT⁴⁷ of <3 or 4 U/L in most species except Amazon parrots, which had a high normal value of 10 U/L.⁴⁰ Differences in methodologies for measuring GGT may account for the marked differences in reference intervals.

There are numerous reports of birds with bile duct carcinoma or cholangiocarcinoma in which no concurrent increase in GGT activity was reported. 14,18,27,51 It is possible that GGT was not measured, since GGT activity would be expected to increase in these hepatic diseases. The authors did not indicate if GGT had been analyzed in these cases. The clinical utility of GGT in the diagnosis of biliary conditions in birds has not been adequately evaluated.

Globulin

Method

Globulin concentration is calculated by subtracting albumin from total protein. Any error in albumin or total protein measurement will cause error in globulin concentration. Globulins can be separated by plasma gel electrophoresis. When the exact size of the protein of interest is unknown, as is commonly the case in veterinary medicine, the proteins are classified in the alpha, beta or gamma globulin fraction, dependent upon where they band on the gel.

Physiology

Any plasma protein that is not albumin or, in birds, transthyretin (pre-albumin) is classified as a globulin. Plasma globulins that have been identified in the banding pattern of birds are alpha-1-antitrypsin (alpha-1 globulin fraction); alpha-2-macroglobulin (alpha-2 globulin fraction); fibrinogen, beta-lipoprotein, transferrin, complement, and vitellogenin (beta-globulin fraction); and immunoglobulins and complement degradation products (gamma globulin fraction). In oviparous females, vitellogenin and other proteins used in egg formation can increase dramatically during reproductive activity. Thus, the globulin fraction increases more than the albumin fraction, causing the Albumin:Globulin (A:G) ratio to decrease physiologically in some female birds.

Diagnostic Value

In addition to egg formation causing increased globulins, inflammatory disease states frequently result in increased globulins. Acute-phase proteins such as alpha-2-macroglobulin are produced in the liver in response to inflammatory cytokines. Generally in inflammatory states, these acute-phase proteins and immunoglobulins increase while albumin, a negative acute-phase protein, decreases. This results in a decreased A:G ratio. Gel electrophoresis allows the practitioner to examine the banding pattern and determine if the decreased A:G ratio is due to acute or chronic inflammation or egg formation. Banding patterns cannot be used to diagnose specific disease such as aspergillosis or chlamydophila infection.

Decreased globulins result from decreased production such as in liver failure, or increased loss, most commonly due to protein-losing enteropathy.

Glucose

Method

There are several methodologies used to measure glucose that vary between the types of machines used. The normally high blood glucose level of many avian species may fall above the linear range of measurement of some handheld glucometers. The practitioner should know the linear limit of their glucometer, usually found in the

manufacturer's insert. Results above that limit should be written as >linear limit (#). It should be noted that many small handheld units guarantee only 20% coefficient of variation, which means that the number obtained can vary as much as 20% from the actual glucose concentration in the sample.

Most veterinary laboratories use the hexokinase method on a wet reagent analyzer, where NAD is measured at 340 nm after two reactions using hexokinase and glucose-6-phosphate dehydrogenase. This method has an upper limit of 1000 mg/ml in undiluted samples and 2000 mg/ml with automatic dilution. It is therefore the preferred method in avian species.

Lipemia and hemolysis can both increase the measured plasma glucose concentration.

Physiology

There are species differences in the way that birds regulate blood glucose. The insulin content of the pancreas of granivorous species is about one-sixth that of the mammalian pancreas, while glucagon content is about 2 to 5 times greater.25 Pancreatectomy induces hypoglycemic crisis in granivorous birds, but produces diabetes mellitus in carnivorous birds. 40 The finding suggests that while glucagon predominates in granivorous birds, insulin may predominate in carnivorous birds. Although diabetes mellitus in psittacines is attributed to increased glucagon secretion, there have been reports of decreased insulin concentration in a diabetic African gray (Psittacus erithacus) in comparison with a normal bird9 and positive responses to insulin therapy. It is therefore possible that either glucagonemia or hypoinsulinemia are responsible for diabetes in psittacines and other species.

Stress hyperglycemia is induced in birds by high levels of endogenous or exogenous glucocorticoids.

Diagnostic Value

Stress hyperglycemia should be ruled out prior to a diagnosis of diabetes mellitus. Measurement of insulin and glucagon levels in comparison to a control bird should be attempted to determine etiology of diabetes on a case-by-case basis. Etiologies of hypoglycemia should be ruled out using additional diagnostics. Consider the use of a carbohydrate absorption test (xylene or glucose challenge) to rule out underlying malabsorption/maldigestion.

Iron

Method

Care must be taken to ensure that anticoagulant collection tubes do not contain iron, EDTA, oxalate or citrate that bind iron. Some iron methods require serum and

cannot assay plasma. Check with the laboratory prior to submission. There are a variety of methods, including coulometry, colorimetry and atomic absorption spectrophotometry, that are used to measure iron. Colometry involves applying a voltage to a reaction and measuring the amount of energy needed to drive the reaction. It can be performed as a titration with another ion and is generally quite accurate in the measurement of iron. Atomic absorption is unreliable due to matrix interference in serum. Through modification of the serum iron methods, total iron-binding capacity and serum transferrin also can be determined. Ferritin, the storage form of iron that is generally measured to assess total iron stores in mammals, is measured using antibody-based ELISA and RIA techniques that do not cross-react in avian species. Ferritin, therefore, cannot be measured at this time.

Physiology

All living organisms, except possibly *Lactobacillus* spp., require iron.⁵⁷ Aside from meat-based products, most ingested iron is in the less bioavailable ferric form. The ferric form (Fe³⁺) can be reduced to the bioavailable ferrous form (Fe²⁺) by intestinal bacteria. Free iron can catalyze free radical formation from oxygen and nitrogen, and can therefore cause marked cellular and tissue damage. For this reason, plasma and intracellular iron are protein bound. The majority of iron in the body is bound in hemoglobin; however, iron also is bound to transferrin for transport in the plasma, ferritin and hemosiderin for cellular storage, and myoglobin in muscle. Prior to egg laying, iron levels will increase 2 to 3 times normal in some species.²⁸

Diagnostic Value

Serum chemistry results in birds with hemochromatosis may include increased liver enzyme activity, usually AST, which is believed to be due to iron-induced hepatocellular damage. A few anecdotal case reports describe increased serum iron concentration in sick versus control birds. Other studies found no significant correlation between serum chemistry values, serum iron concentration, total iron-binding capacity and unsaturated iron-binding capacity with hepatic iron accumulation, as assessed by histopathology and iron quantification. However, the reference values used in one study were considerably higher than those used in domestic mammals and human beings. Additionally, birds with possible inflammation (eg, leukocytosis, heterophilia and monocytosis) were included in the study.

Although serum ferritin concentration correlates significantly with non-heme iron in the liver and spleen of dogs, cats, horses and pigs, this correlation has not been explored in birds due to the species-specificity of antibody recognition and binding in ferritin ELISAs and RIAs.²¹ Additionally, percentage iron saturation has not been evaluated in birds. Further study of iron status in companion avian species may have the clinical benefit of eliminating invasive liver biopsies as a screening modality for diagnosing hemosiderosis.

Lipase

Method

Many lipase methods including titrimetric, turbidimetric, spectrophotometric, fluorometric and immunological techniques have been described, with no one method recognized as a gold standard. Differences in laboratory values are likely due to differences in methodologies. Be cautious when using reference intervals from the literature to assess a patient.

Physiology

Lipase hydrolyzes glycerol esters of emulsified, long-chain fatty acids. 55 Most lipase produced in mammals is produced in the pancreas, however activity also is seen in gastrointestinal mucosa, leukocytes and adipocytes. Tissue enzyme contributions have not been investigated in birds.

Diagnostic Value

In mammals, lipase concentration in plasma and effusive fluid is most commonly used to investigate pancreatic disorders, usually pancreatitis. It is generally more useful in acute forms of the disease, as more chronic lesions are associated with increased parenchymal destruction that results in lower levels of lipase. Renal disease can result in mildly increased plasma levels due to decreased clearance, but increases are generally not as dramatic as with pancreatitic disease.

Phosphorous

Method

In the most common method used, phosphate reacts with ammonium molybdate to form a phosphomolybdate complex. The colorless phosphomolybdate can be measured photometrically at 340 nm or can be reduced to molybdenum blue and measured at 600 to 700 nm. Measurement in the 340-nm range is more likely to be affected by hemolysis, icterus and lipemia.

Common detergents are frequently contaminated with phosphate and it should be ensured that phosphate is measured using only new, unwashed equipment. Delayed plasma separation or hemolysis will significantly alter plasma phosphorus levels.

Physiology

Inorganic and organic phosphorus both have numerous vital roles in the body. Inorganic phosphate is complexed with calcium to form hydroxyapatite in beak and bone. This structural form also functions as a phosphate storage compartment. The dissolution of phosphoric

acid in plasma is an important buffering system that complements the carbonic acid buffering system. Chemical energy in all cells depends on the high energy bond in ATP and (guanosine triphosphate) GTP (both triple phosphate molecules). Organic phosphate is an essential component in phospholipid membranes and nucleic acids, and is critical for several important enzyme systems.

Diagnostic Value

In oviparous species, increased phosphorus and calcium concentrations are observed during egg formation in females. Generally, these occur together and the calcium: phosphorus ratio stays above one in healthy individuals. If the calcium:phosphorus ratio is below one, renal or other disease (ie, primary or secondary hyperparathyroidism) should be investigated. Both hyperphosphatemia and hypophosphatemia have been associated with renal disease in birds. This electrolyte flux may represent acute and chronic forms of renal disease as in mammals. Alkalosis will cause flux of phosphate into the cell and an apparent hypophosphatemia. Some acidosis, such as diabetic ketoacidosis, results in catabolism of phosphorylated compounds in the cell with excretion of phosphate at the kidney and whole-body phosphorus depletion.

Total Protein

Method

There have been several articles written on refractometer versus biuret analysis of total protein. 1,41,42,50 The biuret method is a more specific chemical reaction where peptide bonds are reacted with cupric ions to form a colored product measured spectrophotometrically at 540 nm. The total protein value determined using a refractometer is frequently inaccurate in companion avian species due to interference by high concentrations of other light-refractive compounds in plasma, such as chromagens, lipids and glucose. Studies in chickens, turkeys and ducks have shown good correlation between protein concentrations obtained by refractometer^d and biuret methods.^{1,50} These species tend to have lower blood glucose values than most psittacines and smaller birds. Correlation studies in avian species with high blood glucose levels, such as pigeons, have shown marked discrepancies between refractometer and biuret methods, however, a different brand of refractometere was used, that may have contributed to the difference in results. 41,42 There is marked variation in normal blood glucose levels in avian species. The biuret method is the most accurate method to quantify total protein in the clinical setting, where samples from many different species may be evaluated.

Physiology

The body contains thousands of proteins each having

one or more functions. An increase in plasma proteins may be observed in egg-laying females.

Diagnostic Value

Though not adding information about specific disease etiology, total protein is important information used to establish supportive care. Decreased total protein may indicate the need for colloid (hetastarch) supplementation and incite a search for an underlying protein-losing nephropathy, enteropathy or liver failure. In cases of increased total protein, reproductive activity should first be ruled out in females and then dehydration or an underlying inflammatory disease state should be investigated.

Uric Acid

Method

The most commonly used method is the uricase method where uric acid is catalyzed by uricase to allantoin. The decrease in concentration of uric acid is measured at approximately 285 nm.

Physiology

Uric acid is the major nitrogenous waste product of birds. It is hypothesized that this has evolved due to oviparity.40 Embryonic and fetal development occur within a closed compartment, the egg, that lacks diffusion of nutrients and waste. Uric acid is relatively inert and substantially less toxic than ammonia or urea, thus ensuring a viable hatchling. Uric acid (an oxidized form of the purine, hypoxanthine) is synthesized predominantly in the liver from purine metabolism, with a small amount of synthesis occurring in the renal tubules. Approximately 90% of uric acid is secreted in the proximal convoluted tubules in the normal bird.²⁰ This percentage can be markedly altered in pathologic conditions. Uric acid is passed to the cloaca and then may be retropulsed to the rectum and ceca, where it may be broken down by bacteria and reabsorbed.^{7,8}

Diagnostic Value

Due to active renal tubular secretion, blood uric acid levels are not notably affected by dehydration until GFR is decreased to the point that uric acid is not moved through the tubules, which may occur in severe dehydration. Raptors and penguins have higher reference values for uric acid, and marked increases in plasma uric acid concentration may be observed postprandially. Therefore, sampling of carnivorous birds should be performed after a 24-hour fast. Fasting also will decrease the likelihood of lipemia, which is frequently observed in postprandial samples. Contamination of the blood sample with trace amounts of urates from the skin of birds may lead to extreme elevations in uric acid measurements. Questionable samples should therefore be redrawn and the testing repeated. Once the above etiologies are ruled

out, renal disease should be assessed with urinalysis, radiography, and/or renal biopsy (see Chapter 16, Evaluating and Treating the Kidneys).

Urinalysis

Osmoregulation is accomplished by contributions from the kidneys, intestinal tract, salt glands and, to some extent, the skin and respiratory tract. 19,20 Urine can be actively retropulsed from the urodeum to the coprodeum of the cloaca and then to the rectum and potentially the large intestine, where water can be reabsorbed and electrolytes can be modified. This results in a change in the specific gravity, electrolyte concentrations and bacterial contamination of urine.

Urinalysis is indicated when there is azotemia, uratemia, polyuria/polydipsia, hematuric abnormal urates, or genitourinary masses. Birds with renal pathology will frequently have polyuria, resulting in a urine sample of adequate volume for analysis. Avian urine is generally collected free catch by removal of cage paper and thorough cleaning of the cage surface. A needle and syringe or capillary tube can be used to aspirate urine from the cage bottom and minimize fecal contamination. Ureteral catheterization has been performed, but, requires anesthesia and is difficult.65

Normal urine has a clear fluid component. There is variation in normal urine volume among species that are adapted to different food sources and environments. 10,19 Specific gravity in most clinically normal birds has been reported as 1.005 to 1.020, and avian urine is generally acidic.6 Normal urine sediment is generally composed of uric acid precipitates and crystals, sloughed squamous epithelial cells, <3 WBC/40x field and <3 RBC/40x field, and low quantities of predominantly gram-positive bacteria. Bacteria present in normal samples are attributed to fecal contamination.

The majority of uric acid in avian urine exists as a white to light yellow colloidal suspension made up of small, spherical conglomerates (urates) that range in diameter from 0.5 to 15 μ m.⁶ The urate precipitate is composed of uric acid, sodium and/or potassium, and protein. The precipitate is not measured in the specific gravity of the urine supernatant, and therefore urine specific gravity is lower in birds and reptiles than in mammals. Any protein not reabsorbed in the proximal tubule is generally precipitated with uric acid. Assuming there is no fecal contamination, normal avian urine should not contain protein that can be detected on a urine dipstick.32

Needle-shaped uric acid crystals also may be observed in normal urine. Uric acid crystals polarize and can be tested chemically using the murexide test. A drop of concentrated nitric acid is added to the crystals and heated to evaporation. A drop of ammonia is then added. If uric acid is present, the liquid will turn a mauve color. Adding several drops of sodium hydroxide to a urine sample will dissolve uric acid crystals. This can facilitate the identification of casts, bacteria and cells.

Biliverdinuria, grossly apparent as green urates, is not a normal finding and is most commonly caused by bile stasis due to liver compromise. It also may be seen in birds with hemolytic anemia. Biliverdinuria associated with nephrosis has been described histologically.⁵³ The clinical significance of the described nephrosis is unknown. Prior to diagnosing biliverdinuria, fecal contamination should be assessed by measuring urobilingen with a urine dipstick. A positive urobilinogen result supports fecal contamination.

Hemoglobinuria has been documented in heavy metal poisoning, specifically lead toxicosis, in Amazon, Electus and African grey parrots secondary to intravascular hemolysis.¹⁷ Ketonuria is not observed in normal birds. Ketones have been found in the urine of migratory birds, but otherwise support a diagnosis of diabetes mellitus.^{9,63} (See acetoacetate, acetone in the Analytes section).

Even in free catch samples, culture and sensitivity are indicated when bacterial infection (eg, pyuria) is suspected based on clinical presentation or urinalysis results. Renal biopsy and culture also can be performed if inflammation or infection is believed to involve the kidney (see Chapter 16, Evaluating and Treating the Kidneys).

Diagnostic Value of

Endoscopy and Biopsy

MICHAEL LIERZ, Dr med vet, MRCVS, Certified Specialist Poultry-Avian Medicine, Certified Species Conservation

Endoscopy has been used in avian medicine since the 1970s, primarily for determining gender in birds that are not sexually dimorphic. With the advent of acceptable inhalation anesthetics, the safety of this procedure has increased while the stress to the patient has decreased. Unless otherwise noted, the descriptions in this chapter are of psittacine patients and related procedures using rigid endoscopes (Fig 24.1).

Endoscopes are fiberoptic probes that utilize magnification to facilitate visual inspection of internal body structures. Endoscopy can complement imaging modalities such as radiography and ultrasonography. Direct visualization of internal structures by the endoscope affords numerous advantages as a diagnostic tool (Tables 24.1-24.4). There are instances where the use of a semi-rigid or a flexible endoscope is advantageous. Rigid endoscopes are available in a variety of viewing angles (Figs 24.3a-b).

While most endoscopic procedures are minimally invasive, they do require anesthesia for restraint and pain management. Endoscopic visualization performed by an experienced practitioner carries minimal risk. However, the risk increases when more invasive procedures (biopsy, surgery) are performed (Table 24.5). In order to minimize the risk to the patient and maximize the diagnostic information, the practitioner should become proficient with endoscopic location and visualization of internal structures. Cadavers are excellent training tools, as they allow immediate comparison between what is visualized endoscopically and the actual organs or gross necropsy (see Chapter 26, Diagnostic Value of Necropsy).

Table 24.1 | Characteristics of Endoscopes

(see Figs 24.1, 24.2a-c)

Endoscopes	Comments		
Rigid	Best choice for primary scope 2.7 mm diameter, 30° viewing angle, 19 cm length recommended 1.9 mm diameter provides acceptable imaging for most patients and procedures 4.0 mm provides best imaging but is too large for some avian patients Quality varies between manufacturers (Fig 24.1)		
Flexible	Recommended for a second scope Preferred for evaluating proventriculus, ventriculus and oviduct The diameter is most useful, has three ports to accommodate the lens, fiberoptic light bundle, instruments Quality differs between manufacturers (Figs 24.2a-c)		
Semi-rigid ^o	1.2 mm diameter ideal for small patients, small orifices See Chapter 1, Clinical Practice, Fig 1.13		

Note: Diameters of scopes do not include sheaths and their working channels.

Table 24.2 | Light Sources

idale 2-12 Ligiti Society		
Light source	Comments	
Halogen: xenon	Gives the most light	
Computed flash generator	Necessary for 35-mm slide documentation	
Light cable	Must be compatible with the light source	
Otoscope handle	Portable scopes are available that attach to otoscopes Less expensive, most provide adequate illumination	

Table 24.3 | Lenses for Rigid Endoscopes

	•
Lense	Comments
Single lens	Lower-quality image
	Less expensive
Rod lens	Best-quality image
	More expensive

Table 24.4 | Viewing Angles for Rigid Endoscopes

(see Fig 24.3a-e)

Angle	Comments
0°	Natural straightforward orientation Good for examination of the ear canal, oral cavity, crop, trachea Superior for photodocumentation
30°	Forward oblique angle Allows visualization of a larger area by rotating the scope

Table 24.5 | Surgical Equipment Used during Endoscopy

- Small, curved mosquito hemostats Tissue-handling forceps
- Scalpel, #15 blade
- · Needle holder
- Small scissors
- Suture

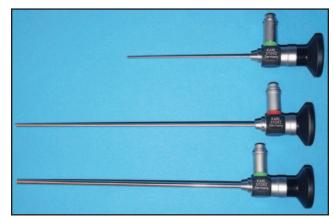

Fig 24.1 | Rigid endoscopes most commonly used in avian endoscopy. Top to bottom: 1.9 mm 0°, 2.7 mm 30°, 4 mm 0°.

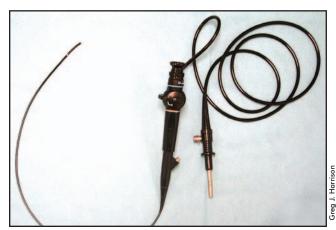

Fig 24.2a | A flexible endoscope allows more maneuverability in viewing lungs and the gastrointestinal system.

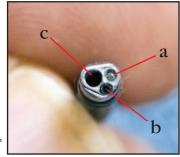

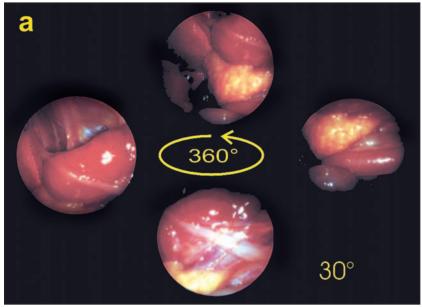

Fig 24.2c | The fiberoptic bundle (a) for light and visualization, the air or flushing port (b), and an instrument port (c) of a 3-mm flexible endoscope.

Greg J. Harrison

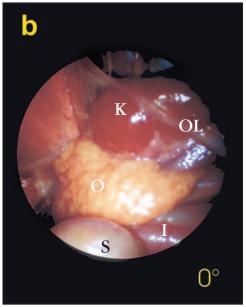

Fig 24.3 | a) The view as seen through a 2.7-mm 30° scope. Turning the scope around its optical axis, a panoramic view is possible.
b) Kidney (K), ovary (O), Ovarian ligament (OL) Intestine (I) and Spleen (S) seen with a 4-mm 0° scope. Only a straightforward view of the organs is possible.

Fig 24.4 | Basic equipment for endoscopic-guided multipleentry surgery in birds. Top to bottom: monopolar sling, scissor, grasping forceps, bipolar forceps for coagulations, trocars.

Table 24.6 | Endoscopic Accessories (see Figs 24.5a-b)

Accessory	Comments
Flexible biopsy forceps	Must match working channel of scope to allow use of forceps without obstructing view 1.8 mm recommended Elliptical cup (deeper cuts) Round cup (recommended for testicular, kidney biopsy)
Flexible grasping forceps	Removal of foreign bodies, granulomas
Infusion/aspiration needle ^a	22-gauge flexible needle inside Teflon catheter ^b Can be used in the working channel Good for aspirating fluid from cysts and direct application of medications (Figs 24.5a,b)
Software	Systems are available to store endo- scopic images in medical records
Endoscopic-guided surgery equipment	• See Fig 24.4
Cleaning and sterilization	Follow manufacturer's instructions Adequate time between patients is necessary to properly sterilize all equipment

Most of the body can be examined using endoscopy. Apart from the visual assessment, tissue sampling is possible using the working channel and biopsy tools (Table 24.6). A sterile sheath is particularly valuable for microbiological sampling (especially of the deeper respiratory system). The sheath prevents contamination of the sample.

New surgical procedures using multiple endoscopes, multiple sites and radical new instruments are being developed (Fig 24.4). The use of a flexible needle can have multiple applications (Figs 24.5α ,b).

Preparation and Contraindications

Duration of pre-endoscopic fasting will parallel that of presurgical fasting for similar procedures. Longer fasts may be required to facilitate visualization of abdominal organs. General anesthetic techniques and requirements are discussed in Chapter 33, Updates in Anesthesia and Monitoring.

Birds with bleeding dyscrasias are at heightened surgical risk, especially when an organ biopsy is performed. The

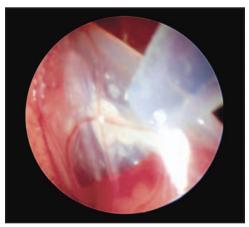

Fig 24.5a | The Teflon tube of the flexible needle is an excellent tool for the endoscopic-guided application of medicine directly to lesions such as this air sac granuloma.

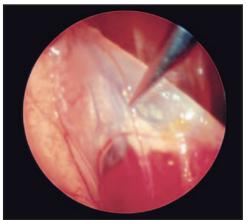

Fig 24.5b | The flexible needle can be used for aspiration, biopsies, penetrations and application of medicine. Here, it is ready to penetrate a granuloma for a needle aspirate.

presence of cystic structures within the coelom, organomegaly or the presence of any fluid will complicate the procedure and increase the risk to the patient. Fluid should be carefully drained or reduced with diuretics prior to endoscopy. Obesity often reduces the view in the body cavity, increasing the risk of organ damage.

Coelomic Laparoscopy **Studies**

LEFT LATERAL APPROACH

The endoscopic approach to the coelomic cavity depends on the diagnostic goal of the procedure (Fig 24.6) and the results of previous imaging studies. The approach caudal to the last rib is ideal for exploration of the entire coelom (Fig 24.7). Due to the presence of an ovary in most avian species on only the left side, approach from the left is generally utilized to allow visualization of female reproductive structures (see the section on gonads later in this chapter). The anesthetized bird is placed on its right side, with the left wing extended dorso cranially. The left leg may be pulled either cranially or caudally. The following description is for the approach with the leg extended caudally (Fig 24.8).

Orientation to the surgical site is provided in Figs 24.9-24.11. A small incision is made in the skin, followed by a caudal reflection of the muscle layers with curved forceps. Penetration into the air sac is accompanied by a palpable and sometimes audible pop. The use of blunt instruments for this penetration cannot be overemphasized. Sharp instruments may damage underlying tissue. The caudal thoracic air sac is most often penetrated, however, the abdominal or cranial thoracic air sacs also

may be entered (Figs 24.12a,b). Some clinicians prefer to enter between the ribs. This is best accomplished by using a curved mosquito hemostat to elevate the ribs prior to penetration. However, using this technique the intercostal muscle is damaged, which is a disadvantage. The direction of penetration should be toward the cranial rib (remaining laterally positioned) to avoid the liver. The scope is stabilized with the tips of the forefinger and thumb while the hand rests on the table (Fig 24.13).

The scope is advanced between the legs of the forceps. The air sacs will then be visible. Clear air sacs allow visualization of the gonad, the adrenal gland, and the cranial division of the kidney, through the abdominal air sac (Fig 24.14). Cranial to this triad is the left lung. In larger birds, the scope may be advanced through the ostium between the lung and air sac to examine the bronchi (Figs 24.15-24.17). The medial lung, heart and liver can be seen as the scope advances cranially into the cranial thoracic air sac.

The ureter, uterus, and ductus deferens are seen ventral to the kidney, and intestinal loops come into view if the scope is directed ventrally from the original entry site. The proventriculus/ventriculus, liver and often the spleen may be visualized when the scope is directed cranioventrally. The punctured air sacs close rapidly and heal uneventfully. The skin incision can be closed with sutures or tissue glue.

A similar approach to the coelom is made by entering caudal to the pelvic limb, which is pulled cranially. The incision is made caudal to the last rib. With this approach, there is less chance of entering the cranial thoracic air sac.

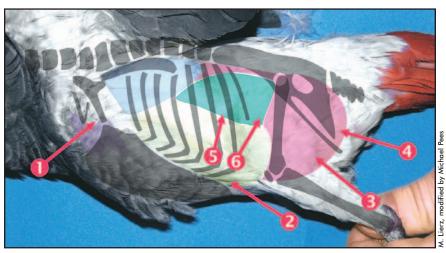

Fig 24.6 | The various endoscopic entry sites overlying the artist's rendition of bones with colored areas representing the various air sacs encountered in endoscopy. Blue represents the intraclavicular, yellow the cranial thoracic, green the caudal thoracic and orange the abdominal air sacs.

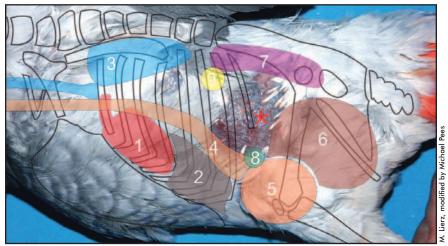

Fig 24.7 | An artist's rendition of the organs encountered in endoscopy from the left lateral aspect. 1) heart 2) liver 3) trachea and lungs 4) proventriculus 5) ventriculus 6) intestines 7) kidney 8) spleen 9) adrenal-gonad area. The red star is a typical entry location.

Fig 24.8 | Right lateral recumbency, left leg caudal. This bird is malpositioned; not being in a true lateral, which is critical for organ relationships. Secondly, it can be seen that in this blue crowned conure the area in front of the leg has a thick fat pad (arrow) that has to be penetrated to reach the musculature.

Fig 24.9 | The middle of a triangle formed by the spine (1), m. iliotibialis (2) and last rib (3); the red arrow represents the most common lateral point of entry for laparoscopy.

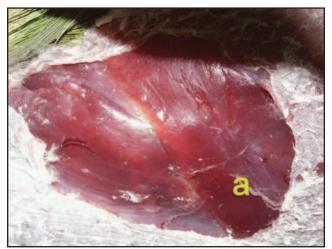

Fig 24.10 | The muscle iliotibialis (a) overlies the point of entry, demonstrated on a dead bird with skin removed.

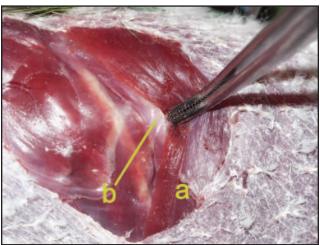

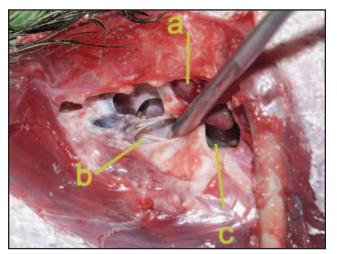

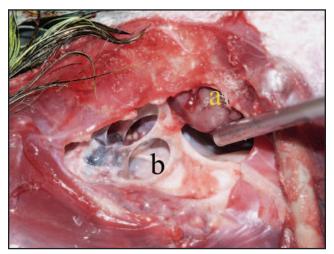

Fig 24.11 | Using a curved forceps, the m. iliotibialis (a) is reflected caudally and the underlying fascia is penetrated caudal to the last rib (b), as is demonstrated here on a dead bird with skin

Figs 24.12a,b | Entering the body cavity caudal to the last rib usually places the scope into the caudal thoracic air sac (b). Changing the route of penetration slightly, the scope is guided into the abdominal air sac (c) where the kidney (a) is located. One must penetrate the confluent wall of the medial aspect of the caudal thoracic air sac and the left lateral wall of the abdominal air sac.

Fig 24.13 | Correct anchoring of the tip of the scope. The hand should always be in contact with the bird while the wrist is rested on the table.

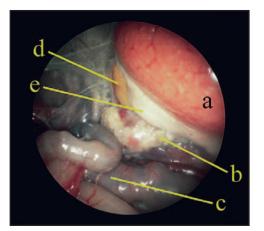

Fig 24.14 | View into the abdominal air sac. Kidney (a), ovary (b), intestine (c), adrenal gland (d), ureter and oviduct (e).

Fig 24.15 | The opening from the caudal thoracic air sac into the lung (aperta) allows retrograde endoscopy of internal structures of the lung.

Fig 24.17 | The endoscope has been advanced into the horizontal secondary bronchi that branches from the left or right primary bronchi. The honeycomb structure of the lungs is seen. This view cannot be appreciated via the trachea due to the diameter restrictions of the syrinx, the fragility of the primary bronchi and the acute angle at the origin of the secondary bronchi.

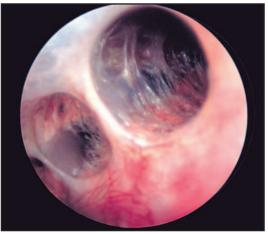

Fig 24.16 | Lung tissue viewed from the caudal thoracic air sac. The bronchi and lung parenchyma are clearly visible.

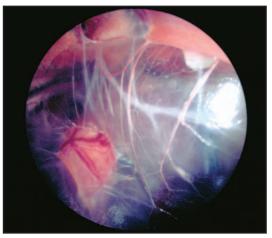

Fig 24.18 | The ideal air sac is transparent. Minor blood and lymph vessels are commonly visible in pet and aviary birds.

VENTRAL MIDLINE APPROACH

The bird is positioned in dorsal recumbency and a ventral midline approach to the coelom is made. A layer of fat may be present just under the linea alba in the area directly caudal to the sternum. Care must be taken on smaller birds not to inadvertently penetrate the duodenum or pancreas. The duodenum, pancreas and central liver can be examined from this approach.

Air Sacs

Normally the air sacs are transparent, although a few vessels may be present (Fig 24.18). Fatty infiltrates may be noted during routine examination without associated pathology. Opacity and small vessels in the wall of an air sac are early signs of inflammation (Fig 24.19). Other abnormalities of the air sacs include increased vascular-

ity, thickened walls and granulomas (Fig 24.20). These changes may be due to infectious processes, or to inhalation of respiratory irritants (ie, smoke, volatile chemicals). In some cases, a definitive diagnosis can be made from visualization, cytology and/or biopsy of air sac lesions (Figs 24.21a-c). Removal or debulking such lesions has been described using laser and radiosurgery via the endoscope.

Lungs and Bronchi

The lungs are dark pink with a prominent reticular pattern. Within the lungs, the anastamosing bronchi are visible (see Figs 24.16, 24.17). Pneumonia will obscure the normally well-defined parenchymal pattern of the lung. A yellow discoloration of the lung tissue is often noted with pneumonia (Fig 24.22). Anthracosis (focal black

Fig 24.19 | Prominent vessels in the air sac, opacity or small granulomas are signs of infections and/or irritation from environmental contaminants (smoke, volatile chemicals).

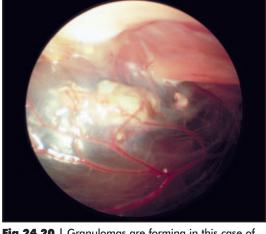

Fig 24.20 | Granulomas are forming in this case of air sacculitis.

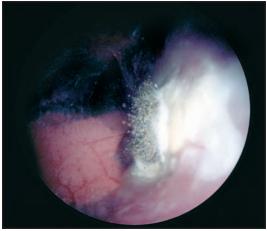

Fig 24.21a | Fruiting aspergilloma in the air sac. This presentation carries a guarded prognosis.

Fig 24.21b | Active aspergilloma in an air sac with fluid exudate.

Fig 24.21c | Removal of an old aspergilloma using a biopsy forceps.

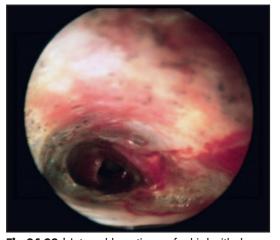

Fig 24.22 | Internal lung tissue of a bird with dyspnea, viewed from the caudal thoracic air sac. Yellow areas and the loss of the typical lung parenchyma are signs of pneumonia. A biopsy to aid in specific diagnosis and treatment is highly recommended. The black spots are soot (anthracosis) and can be found in birds from smokers or cities.

Fig 24.23 | Post-traumatic hemorrhage of the lung.

Fig 24.24 | The normal liver is a brown-red homogeneous color with a sharp border.

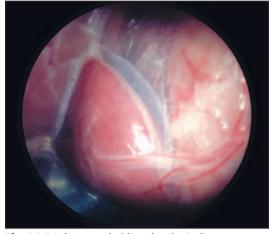

Fig 24.25 | A rounded liver border indicates an enlarged liver. A liver biopsy is often indicated to identify the nature of the hepatomegaly.

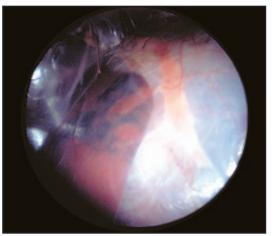

Fig 24.26 | Hematoma of the liver after trauma.

spots) is regularly found in birds from cities, industrial areas or the homes of smokers (Fig 24.22). Bleeding from trauma can be diagnosed by endoscopic examination (Fig 24.23).

Proventriculus, Ventriculus — Serosal Examination

The proventriculus is an elongated, usually white organ located in the ventral coelom, surrounded by the abdominal air sac and the liver. The surface appearance and size of the proventriculus are diagnostically important. An enlarged proventriculus with a glossy surface might indicate proventricular dilatation disease (PDD). Focal bleeding may indicate foreign bodies or infections. The ventriculus cannot always be visualized. In birds with a muscular ventriculus, abnormalities are seldom discernible endoscopically (see Chapter 26, Diagnostic Value of Necropsy).

Liver

The liver is a large organ of uniform brownish red

color. The liver border tapers to an edge (Fig 24.24). A rounded liver border is not normal and may indicate infection or hepatic lipidosis (Fig 24.25). The liver color changes to yellow with fatty liver. Focal bleeding in the liver appears bright red, while hemosiderosis appears dark red that over time can turn black in color (Fig 24.26). Multiple white foci represent necrosis, abscesses or neoplasia (Figs 24.27, 24.28). Pseudomembranous infiltrates of the liver capsule and air sacs may also be due to infection, inflammation or neoplasia (Fig 24.29). Liver biopsies offer very valuable diagnostic information (see Chapter 15, Evaluating and Treating the Liver).

Heart and Pericardium

The lateral approach through the caudal thoracic air sac into the cranial thoracic air sac allows the visualization of the heart and pericardium. Pericardial effusions can be drained utilizing this approach. The normal pericardium is transparent (Fig 24.30α). A milky pericardium is the result of pericarditis. The presence of fat at the heart

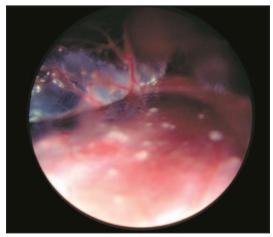

Fig 24.27 | White-yellow spots on the liver, diagnosed as abscesses. Neoplasias have a similar appearance.

Fig 24.29 | Yellow, caseated material present on the liver and air sac due to a bacterial infection.

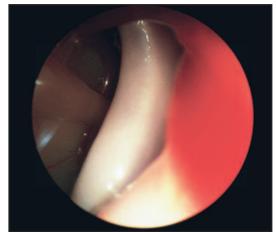

Fig 24.30b | The aorta branching into the carotid artery is seen lying between the costal musculature, the base of the heart and the returning jugular vein.

base and heart apex is normal. An absence of fat is a sign of starvation or chronic disease. The main heart vessels are visible at the heart base as thick white tubes with regular pulses (Fig 24.30b). The cardiac nerve supply can be found emanating from the thoracic vertebrae.

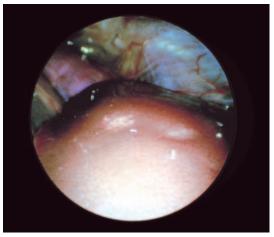

Fig 24.28 | Diffuse necrosis of the liver (histomoniasis).

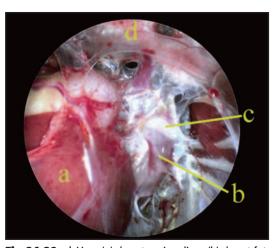

Fig 24.30a | Liver (a), heart pericardium (b), heart fat (c), lung (d) as seen in a normal bird.

Kidney

The avian kidney is divided into three divisions. The adrenal gland and gonad are present at the cranial pole of the kidney (Fig 24.31). The ureter can be seen and, in most cases, traced to the cloaca. The kidney is brownred-orange. Star-shaped collecting tubules filled with urates are often visible on the surface. These structures become hidden in swollen kidneys (Fig 24.32). Yellow to white deposits on the surface of the kidney are often uric acid crystals and may indicate renal gout (Fig 24.33). These foci might occur due to dehydration as well. After rehydration the foci are eliminated, while in the case of gout the foci are still present. Obesity can make the kidney appear diffusely yellow. Abscesses or cysts may appear as large yellow spots (Figs 24.34, 24.35). Neoplasias or other gross abnormalities should be biopsied; assuming that the patient's condition is sufficiently stable (see Chapter 16, Evaluating and Treating the Kidneys).

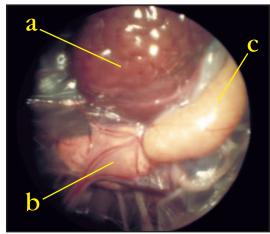

Fig 24.31 | Kidney (a), adrenal gland (b) and testicle (c). Apart from the clearly visible testicles, the absence of a ligament crossing the cranial pole of the kidney represents a male bird. The lumpy nature of the kidney surface is normal for swans.

Fig 24.32 | A swollen kidney as seen in acute nephritis. Note the lack of predominate stellate vasculature pattern associated with the renal glomeruli.

Fig 24.33 | Uric acid deposits within the kidney. If this situation remains after several applications of intravenous fluids, renal gout is likely.

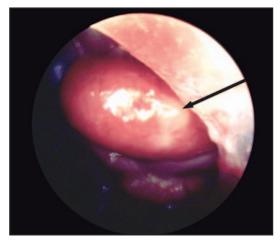

Fig 24.34 | Renal cyst. Abscess or neoplasia are possible differential diagnoses.

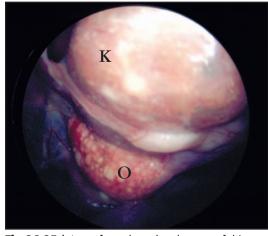

Fig 24.35 | Apart from the color changes of this kidney (K), multiple yellow foci are visible. The typical renal structure is no longer detectable. Histological examination of a renal biopsy showed a pyelonephritis. The ovary (O) has many involuted follicles.

Gonads

The left lateral approach is best for viewing gonads because hens generally lack a right ovary. Right ovaries may be present in juvenile birds, especially in accipiters. Gonads are present ventral to the cranial poles of the kidneys.

DNA methods are available for sexing most monomorphic avian species and are less invasive than surgically sexing. Endoscopic sexing has the advantage of allowing direct visualization and evaluation of the gonads and other organs. Sexual function can be estimated and any damage from sterilization or castration can be observed. The normal appearance of the gonads varies between species. The right side should be examined if the gonads are not clearly observed or discernible as to either ovary or testes, or if presumed abnormalities are present. Gonads increase in size during sexual activity (Figs 24.36-24.38). Gonads can be small due to stress, malnutrition,

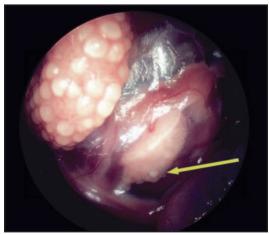

Fig 24.36 | In juvenile birds, the rudimentary ovary on the right side still might be visible, sometimes showing single follicles (arrow). The normal left ovary is at the 9-11 position.

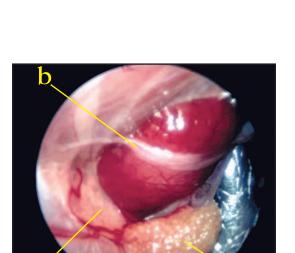

Fig 24.38 | A cluster of follicles makes identification of the ovary (a) easy. More important is the detection of the suspensory ligament (b) of the ovary. It crosses the cranial pole of the kidney. Apart from sexing, evaluation of the ligament is important to judge the possible breeding performance of the bird. Adrenal gland (c).

Fig 24.37 | Secondary or tertiary follicles dramatically increase in size during the reproduction cycle. Pathological alterations such as inflammation or neoplasias might lead to similar findings. A detailed anamnesis indicating sexual display behavior may indicate an active ovary. If a large follicle is very close to the tip of the endoscope, the follicle can be easily confused with a testicle.

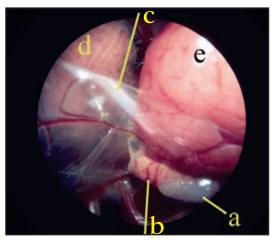

Fig 24.39 | In juvenile birds, the ovary (a) might be difficult to detect. Only the suspensory ligament (c) at the cranial pole of the kidney (e) characterizes the female bird. Lung (d), adrenal (b). Small ovarian follicles are not an accurate estimation of age or reproductive ability.

lack of nesting stimuli or immaturity.

Female Birds

The ligamentum dorsale oviductus (suspensory ligament) from the ovary crosses the cranial pole of the kidney coursing toward the uterus (Fig 24.38). Lacking visualization of a well-defined gonad, this ligament is the main evidence for sexing the bird as a female. The ovaries can be difficult to detect in juvenile birds (Fig 24.39). When examining breeding birds this ligament must be carefully assessed. In cases where this ligament is damaged or absent, the breeding performance of the bird is questionable (Fig 24.40). If this ligament is cut in juvenile birds, they will not lay eggs. A large uterus may indicate previous egg laying or pathology. Inactive ovaries may be flat with a cobblestone appearance, while active ovaries may appear as a cluster of spheres. The size and number of visible follicles will vary with the age and reproductive status of the hen. Immature ovaries are sometimes difficult to distinguish from testicles. The ovary is generally an off-white, yellowish color, but pigmentation (usually black) occurs in some species (Fig 24.41). In addition, the entire uterus should be evaluated.

Male Birds

In male birds there is no ligamentum dorsale oviductus

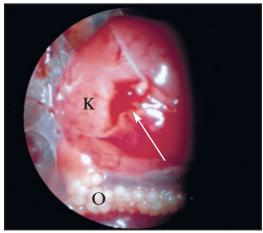

Fig 24.40 | The ovary (O) is clearly visible and the suspensory ligament is missing. This bird cannot be recommended for breeding. The kidney (K) has just been biopsied (arrow).

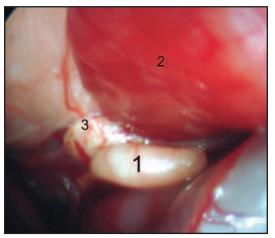

Fig 24.42a | The teste (1) is at the cranial pole of the kidney (2) and close to the adrenal gland (3).

Fig 24.41 | Some avian species have melanistic gonads, as is seen in this ovary.

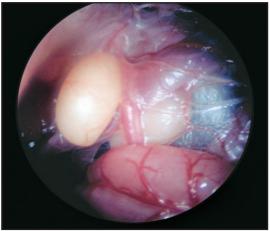

Fig 24.42b | Both paired teste are pictured here. With increased size of the left testicle or opacity of air sacs, the right testicle may be obscured from view.

(Figs 24.42a,b). The paired testicles are normally oval shaped with one to three faint vessels crossing the surface. In birds with clear air sacs, both the left and right testicles may be visualized from the left lateral approach. In some species the testicles are pigmented (eg, Cacatua, some macaws and wading birds). The torturous course of the ductus deferens makes it distinguishable from the ureter (Fig 24.43). The size of the testicles, epididymides and ductus deferens vary with the species, size, age and breeding condition of the individual bird (Fig 24.44). The breeding potential of a male bird normally cannot be assessed by visual observation of the male anatomy. If a reproductive problem is suspected, a testicular biopsy is suggested (Fig 24.45).

Adrenal Gland

Adrenal glands vary in color, size and shape (see Fig 24.42a). They may be confused with immature or inactive gonads. If the gonads are well-developed, the adre-

nal glands may be obscured. The adrenal glands are usually located immediately cranial to the gonads. Changes in size or increased vascularity of the adrenal glands may indicate stress or disease (Fig 24.46).

Intestine

Visible pathologic changes of the intestinal serosal surface are uncommon. Coelomic filarial worms are a rare finding in captive bred psittacines, but are regularly seen in birds of prey (Figs 24.47, 24.48). The intestine has a smooth surface covered with many vessels. The generally redishgray color varies according to the intestinal fluid. White foci may be a sign of previous penetration by endoparasites. Both thinning and thickening of the intestinal wall are signs of enteritis. Thinning can be appreciated endoscopically from the visibility of intestinal contents.

Necrosis of the intestine wall might be visible in cases of clostridiosis or coccidiosis. Enlarged ceca filled with caseous yellow material could indicate histomoniasis.

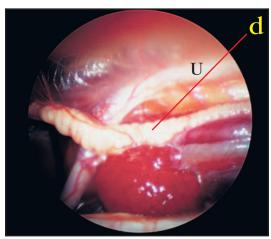

Fig 24.43 | Ductus deferens (d) and ureter (U) in a sexually active male.

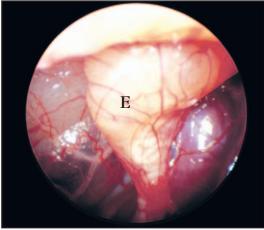

Fig 24.44 | Epididymis (E) of a sexually active male.

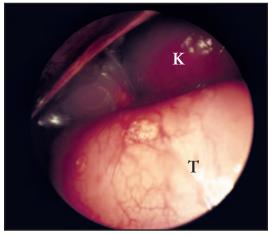

Fig 24.45 | A testicle (T) with a structural abnormality that would indicate the need for a biopsy. Kidney (K).

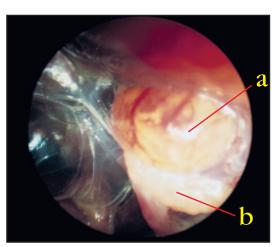

Fig 24.46 | Enlarged adrenal glands (a) appear in cases of stress or diseases. Juvenile ovary (b).

Pancreas

The pancreas lies within the duodenal loop (Fig 24.49). The pancreas is a white-yellow color with a homogeneous matrix. Color changes, glassy appearance or an uneven surface often accompany pathologies and may warrant biopsy (see Chapter 26, Diagnostic Value of Necropsy).

Spleen

Psittacine spleens are round, purplish and often speck-led (Fig 24.50). The spleen is located at the dorsal aspect of the proventricular/ventricular junction on the right side from a left lateral approach. Splenomegaly (immune response), yellow appearance (fatty spleen) and multiple white foci (necrosis) are possible pathological alterations (Figs 24.51, 24.52). Chlamydophilosis and other bacterial diseases would be included in the differential. The spleen can be biopsied utilizing the same precautions as in mammals.

Tracheoscopy Studies

TRACHEA AND THYROID GLAND

The trachea and thyroid gland can be approached via the cervical branch of the cervicocephalic air sac, the clavicular air sac or through the coelomic cavity. The thyroid gland is visible as an elliptical pink structure attached to the trachea near the syrinx (Fig 24.53). Alterations in size or a shiny appearance are considered abnormal and a biopsy may be indicated.

ENDO-TRACHEAL EXAMINATION

Endoscopic examination of the tracheal lumen is accomplished by extending the patient's neck and gently advancing the scope through the larynx and down the trachea (Fig 24.54). Unless the procedure is very rapid, an air sac breathing tube is necessary (see Chapter 33, Updates in Anesthesia and Monitoring). Many endoscopes are equipped with a protective sheath. Removal

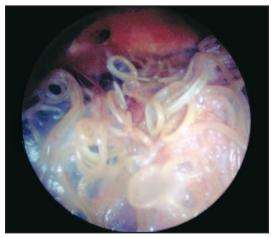

Fig 24.47 | Serratospiculum sp. in the air sac in a falcon.

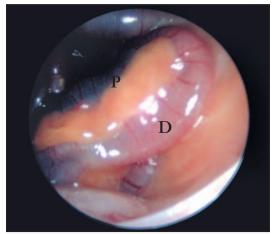

Fig 24.49 | The pancreas (P) identified in the duodenal loop (D). The pancreas should have a homogeneous structure and color.

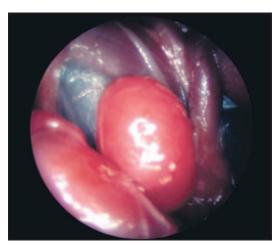

Fig 24.51 | Enlarged spleen of a bird with psittacosis.

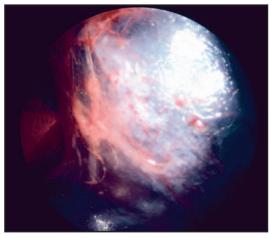

Fig 24.48 | The same bird as Fig 24.47 12 days after treatment with ivermectin. The dead worm can easily be confused with a bacterial infection.

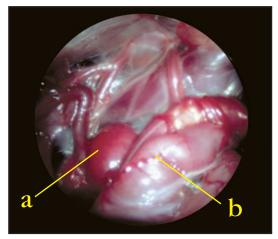

Fig 24.50 | Using the left lateral approach, the spleen (a) is accessible from the abdominal air sac by pushing the proventriculus in the caudal-ventral direction to expose the right side of the proventriculus. The psittacine spleen is round and similar in color (redbrown) to the kidney and liver. Intestine (b).

Fig 24.52 | Pale color changes and enlargement of a spleen.

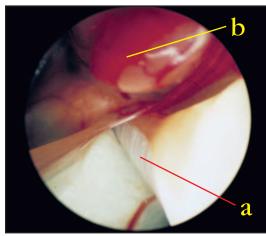

Fig 24.53 | The thyroid gland on the carotid artery adjacent to the trachea as seen from the interclavicular air sac. A laparoscopic approach may be used by pushing the scope cranial, passing over the heart ventrally and following the trachea (a). The thyroid gland (b) can be visualized.

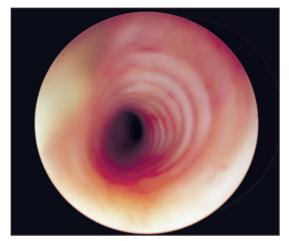

Fig 24.55a | Normal trachea.

of this sheath will decrease the scope's diameter and enable its introduction into the trachea of smaller birds. Unfortunately, this also increases the chance for damage to the endoscope. An unsheathed 1.2-mm scope^a can allow visualization of the trachea of birds the size of canaries and finches (Fig 24.58). Without the sheath, the tracheal lumen can be examined, but no instruments can be introduced into the visual field in such a small patient. Evaluation should be made of the tracheal color, and mucosal texture. The mucosa of the trachea and the bronchi are light pink and glistening. The tracheal rings are clearly visible (Fig 24.55a). In cases of tracheitis, the mucosa becomes red and swollen, making the rings less obvious (Fig 24.55b). Tracheal exudates, when present, should be collected for cytology and culture. Possible abnormalities of the trachea include strictures, tumors,

inflammation, parasites, fungal granulomas and foreign

Fig 24.54 | Performing a tracheobronchoscopy. The neck of the bird must be fully extended. A beak speculum allows a better view and is safer for the scope in case the bird wakes up and attempts to bite the instrument. Anesthesia can be delivered via an air sac tube.

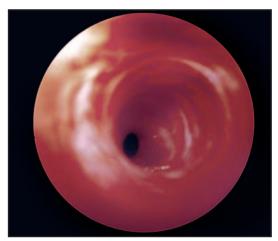

Fig 24.55b | A case of severe tracheitis. The tracheal rings appear distorted due to the mucosal swelling, sloughing and hemorrhage.

bodies (Figs 24.56, 24.57). The tracheal diameter typically decreases toward the syrinx. The narrowed diameter and the tracheal bifurcation into the main stem bronchi make this area particularly prone to fungal granulomas and foreign bodies. Some degree of post-examination hyperemia of the trachea is normal.

Acute dyspnea warrants endoscopic tracheal examination once the patient is stabilized. Hemorrhage of the tracheal mucosa may be seen with polytetrafluoroethylene toxicosis. More pronounced pathology would be expected in the lung parenchyma with this condition.

Respiratory parasites often can be visualized with the endoscope (Figs 24.57, 24.59). If mites are suspected and not visualized, swabbing the scope onto a sterile slide and examining the slide microscopically may reveal tracheal mites.

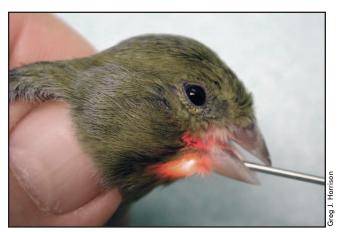

Fig 24.58 | Endoscopy of a canary trachea with a 1.2 mm semiflexible endoscope^a.

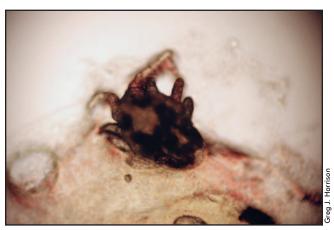

Fig 24.59 | A canary tracheal mite under 100x. This mite was obtained from the endoscope tip. The mites in the trachea were not visualized during endoscopy.

Pharyngoscopy and Upper GI Studies

OROPHARYNX

Sufficient anesthesia or restraint is necessary to prevent damage to the endoscope by the bird's beak. In addition, the use of a beak speculum is advantageous. While under anesthesia, the bird is held in a ventral recumbency position and the neck is fully extended (Fig 24.61). This position allows endoscopic examination of the inner surface of the beak, oral cavity, choana, rhinal cavity, tongue and larynx. The shape of the tongue differs from species to species. The infundibular cleft should be free of swelling and debris. Check the entire oral cavity for signs of pathology (Tuble 24.7).

RHINAL CAVITY

The rhinal cavity can be entered from the choana and the turbinates examined. The operculum prevents the passage of a scope through the nares. The points used to perform an infraorbital flushing technique also can be entered endoscopically.

ESOPHAGUS, CROP, PROVENTRICULUS, VENTRICULUS MUCOSAL EXAMINATION

Examination of the esophagus, crop and proventriculus via the oral cavity is a common procedure (Fig 24.62). As the esophagus, crop (Fig 24.63) and proventriculus are hollow organs, insufflation is necessary for visualization.

Table 24.7 | Common Oral Pathology in Psittacines

- Squamous metaplasia
- Keratinized debris
- Blunting of choanal papillae
- Plaques
- Fungal or yeast colonization
- Parasites: trichomonads
- · Bacterial infection
- Oral papillomas: most common in Ara spp.
- Oral neoplasias: fibrosarcoma, squamous cell carcinoma
- Trauma
- Ulcerations

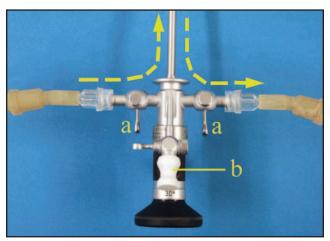

Fig 24.60 | For upper digestive system endoscopy, one uses a sheath with a working channel, here with an endoscope inserted. Hollow organs can be insufflated and flushed using liguids. Tubes for infusion liquids can be attached to the liquid-in and liquid-out taps (a). The arrows demonstrate the direction of the flow of liquids. A port for flexible instruments (grasping biopsy forceps, needle, scissors or various brushes) (b) is shown above the viewing eyepiece.

Fig 24.61 | When performing a gastroscopy, the head of the bird must be in a position lower than the body. Aspiration of liquids into the lungs is then easier to avoid. Tracheal intubation of the bird during anesthesia aids in the prevention of aspiration.

Fig 24.62 | Normal esophagus of a chicken.

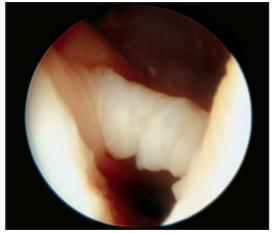

Fig 24.63 | Endoscopic view at the entrance of the crop in a chicken. The oblong structure is the wall between the esophagus and the crop. The other opening is the entrance to the crop.

Prior to gastroscopy, a fasting period is important to allow maximum viewing without the presence of food. Insufflation with air or sterile fluids is commonly used for positioning and advancement of the endoscope. Sterile fluids allow the flushing out of debris and subsequent dilation of the GI tract. This greatly aids in visualization. It is important that the fluid be warm to the touch to avoid decreasing the body temperature of the bird. A working channel is necessary to aim the washing solution. This working channel should have two taps, one for fluids in and one for fluids out (see Fig 24.60). The third port is ideal to allow simultaneous passage of a biopsy or grasping forceps. The fluid inlet is attached to an infusion bag or bottle positioned at a higher elevation. A larger infusion tube is connected to the fluid outlet leading to a collecting container. The two taps allow accurate control of the amount of fluid within the digestive system, expanding the organs as needed for examination. The fluid outlet is closed and the selected portion of the GI tract is dilated until good visualization of the mucosa is achieved. The fluid outlet is then opened in order to flush out mucus and small particles. Opening the fluid inlet again can increase the pressure. To avoid aspiration, fluid should not be allowed to exit the digestive tract through the oral cavity, which could and often does lead to the contents being inhaled. Occlusion of the scope and esophagus to retain the infused air or fluid in the crop can be easily accomplished by placement of digital pressure on the scope and esophagus. Although the tracheal rings are solid in birds, caution

Fig 24.64 | Psittacine cloacal mucosa visualized using liquid insufflation.

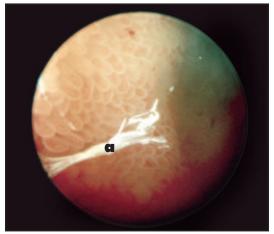

Fig 24.65 | Urates (a) emanating from an ureter on the cloacal surface.

should be used to prevent restriction of normal airflow. In addition, the bird should be positioned in ventral recumbency with the head lower than the body. An endotracheal tube should be in place (Fig 24.61).

The mucosal surfaces of the esophagus and the crop vary between species. The mucous membranes of the esophagus, crop and proventriculus are a homogeneous pink (Fig 24.62). The mucosa of the esophagus is usually smooth; the crop has furrows and the proventriculus papillae (Fig 24.63). Focal dark red or bleeding areas are signs of irritation, which can be due to foreign bodies, infections, ulcerations, or neoplasia. A yellow coating of the mucosa can be seen with trichomoniasis, candidiasis, the diphtheric form of avian pox or vitamin A deficiency or excess. If there is a loss of the proventricular mucous membrane's normal color it might be a sign of a wall suggesting PDD. Biopsy of the proventriculus or the crop and submission for histopathology may confirm a suspected diagnosis of PDD. However the significant risk of dehesience must be considered prior to obtaining a proventricular biopsy. To evaluate the proventriculus in larger psittacines, it may be necessary to introduce the scope through an ingluviotomy incision. A preferred location for this incision is to the left and somewhat dorsally, to avoid postoperative pressure on the crop incision from ingesta. An area of reduced vascularity is ideal. The scope is introduced and advanced carefully into the thoracic esophagus, continuing caudally to the proventricular lumen. This procedure is useful for proventricular biopsies and retrieval of foreign bodies. A flexible scope is mandatory to evaluate a fragile proventriculus (eg, normal lories, large macaws and all cases of PDD) or all ventriculi.

Cloacoscopy Studies

CLOACA

The endoscope simplifies cloacal examination. Insufflation is necessary for viewing to maintain an adequate distance between the scope and tissues under examination. A soft rubber feeding tube may be used, with digital pressure applied around the scope barrel to retain the air or fluid.

When performing a cloacoscopy, the bird is placed in dorsal recumbency and the endoscope is inserted with its working channel. Insufflation is usually done using fluid (see description at Esophagus, Crop, Proventriculus, Ventriculus - Mucosal Examination, above). Feces and urine are almost always present and should be washed out for optimal visualization. The mucosal surface is pink with ureteral papillae (Fig 24.64). Urine can be seen emanating from these ostia of the ureters (Fig 24.65). Hyperemic cloacal membranes are indicative of inflammation or infections. Rough and red raised areas (cauliflower shape) are suggestive of papillomatosis. Inside the cloaca, the openings of the ureters, the rectum and, in female birds, the uterus can be viewed. The oviduct can sometimes be entered and the caudal chambers investigated. The occurrence of fresh blood within the feces is a clinical indication for cloacoscopy, as it may originate from the cloaca, the intestine, the ureters or the uterus.

Otoscopy Studies

EAR

In most species, feathers conceal the opening of the ear canal. The external orifice can vary from <2 mm in small

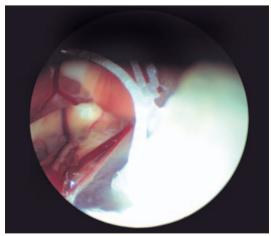

Fig 24.66a | The brachial plexus is visible craniallateral to the heart.

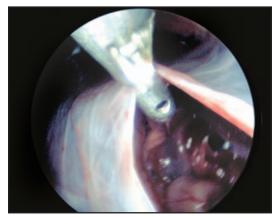

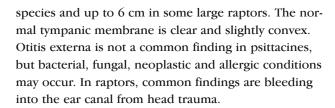

Fig 24.67 | In case of a pansystemic airsacculitis (here milky), the entrance of the scope is the site of choice for a biopsy.

Nerve Studies

The nerves of the brachial plexus are seen anterior and lateral to the heart (Fig 24.66a) The sacral pluxus sometimes visible dorsal to the kidney (see Fig 24.66b). Ed Note: Harrison has used endoscopy to evaluate nerve damage. Muscles, nerves, vessels, tendons and ligaments can be examined using the endoscope. In cases of trauma, air or fluids can be injected subcutaneously to provide a path for the scope to follow anatomical structures into the area of trauma. This technique could be useful to investigate brachial plexus evulsion, nerve transection, thrombi, emboli, and traumatic damage to soft tissue.

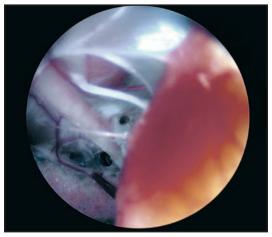

Fig 24.66b | Plexus sacralis dorsal to the kidney.

Fig 24.68 | In case of a grossly abnormal liver, a biopsy should be performed at the liver border.

Endoscopic-guided Biopsies

Coordinating the endoscope and the biopsy instrument can be challenging. The advent of sheaths that are now provided with many endoscopes has simplified this procedure by allowing the biopsy forceps to approach the site without changing the field of vision. The small size of the biopsy forceps used for these procedures usually precludes serious hemorrhage. Endoscopic-guided biopsies allow sampling of organs under direct visualization (Fig 24.67). In general, biopsies of the lung, air sac, liver, kidney, spleen, gonads, proventriculus, ventriculus, thyroid gland and mucosal membranes of esophagus, crop and cloaca are possible using a biopsy forceps within a working channel. Aspiration biopsies are possible using a long, flexible needle with a Teflon cover (see Table 24.6). Puncture of cysts, bone marrow biopsies or lavage sampling are the ideal uses for this needle. In case of a general alteration of an organ, the biopsy should be taken from the organ's border (Fig 24.68). Contraindications of

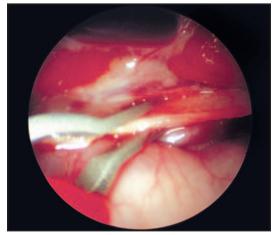

Fig 24.69a | For sterilization of the female bird, the oviduct can be obliterated using a bipolar coagulation forceps. Surrounding tissues must be avoided.

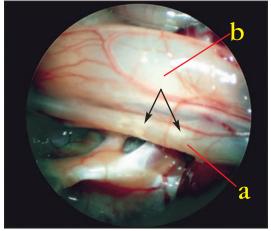

Fig 24.70 | The dichotomy of when to perform female reproductive surgery is amply demonstrated on the immature or involuted side of the question by observing the intimate proximity of the ureter (a) to the uterus (b) in this example. Avoiding collateral damage is imperative. The ureter should be observed for movement of urates (arrows) seen moving during regular contraction cycles. While on the opposite end of the spectrum, the mature or active uterus has up to a centimeter of distance between these structures in a bird as small as a cockatiel, allowing almost no chance for neighboring tissue damage; hemostasis is the challenge. Vessels increase in length but more significantly in diameter and thickness, creating the imminent danger of life-threatening hemorrhage. Some of these vessels are too large for casual coagulation or less than ideal vessel-clamping techniques, resulting in oozing in the first case or loss of the clip and hemorrhage in the latter.

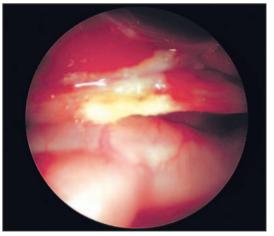

Fig 24.69b | The appearance of the coagulated section of the oviduct that will scar closed.

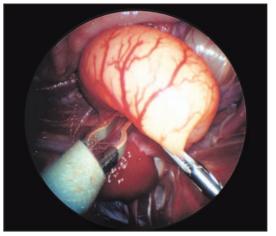

Fig 24.71 | Endoscopic-guided multiple entry for bipolar radiosurgery castration.

biopsies are similar to those mentioned for endoscopy. Endoscopic procedures, in particular tissue biopsies, lead to changes in certain blood values; therefore, planned blood sampling must be performed before endoscopy.

Endoscopic-guided Surgical Procedures

Endoscopic-guided sterilization or castration is possible. This might be indicated in chronic egg laying or birds that are aggressive during breeding season. As castration is quite complex, sterilization represents a quick and easy procedure, as the gonads need not be removed. This can be accomplished using electrosurgery with a bipolar endoscopic forceps (Figs 24.69a,b). Performing this procedure when the bird is sexually inactive reduces the risk of hemorrhage. (Sterilization may hormonally influence behaviors). In juvenile or hormonally inactive females the challenge one is faced with is making the

distinction between the ureter and the quiescent oviduct. The ureter is marked by urates, or its regularly occurring contractions (Fig 24.70). Administering intravenous fluids will increase the likelihood of seeing urates pass down the ureter.

Endoscopic-guided obliteration of air sac granulomas or papillomas in the cloaca is possible. Endoscopic-guided laser diodes have been used to obliterate granulomas within the trachea or air sac. Multiple-entry endoscopic surgery has been developed for resection of tumors or castrations (Fig 24.71). Instruments are guided into the endoscopic field of vision using trocars. Laser or radio-surgery is helpful to maintain hemostasis.

Complication During and After Endoscopy

Hemorrhage is the main complication arising from endoscopy. The kidney can be damaged during penetra-

tion of the air sac at the beginning of the laparoscopy. Perforations of the proventriculus may result in fatal peritonitis. If major bleeding occurs, electrocoagulation, oxidized regenerated cellulose or sterile sticks of cotton wool can be used. The bird should be placed at a 45° angle with the head elevated to prevent blood from entering the lungs. This keeps the blood in the caudal air sacs. If a large entry site has been created, the site may need deep sutures to close the muscles and prevent subcutaneous emphysema. Postsurgical closure of air sac defects is usually not necessary. If emphysema occurs, it should be punctured and deflated regularly until these defects close themselves. When performing endoscopy on multiple subjects sufficient sterilization time for the equipment is imperative to avoid transmission of disease.

Advances in

Diagnostic Imaging

PETER HELMER, DVM, Dipl. ABVP-Avian

Advances in technology have resulted in many different ways of producing and recording diagnostic images. Conventional black and white radiographic images on film continue to predominate, primarily due to widespread access, ease of use, familiarity and relatively low cost. Digital and computerized radiographic images are not widely accessible in private practice. These latter modalities produce a digital image that can be manipulated with a computer to highlight detail and compensate for less than ideal technique settings. Digital technology will become more affordable and more readily available to the private practitioner in the future.

Radiographic Technique

The diagnostic value of a radiograph is directly proportional to the quality of the radiograph. The small size and fine detail of the avian patient necessitate excellent-quality images. Multiple factors influence the quality of a radiograph.²⁰ These factors include motion, the speed of the film, focal spot size, focal spot-to-film distance, object-film distance, the use and type of intensifying screen, and the use of a grid. No technique can maximize the benefits of all of these factors, but a reasonable compromise can be obtained that results in radiographs of high quality.

Motion, even in small amounts, results in significant blurring of the image. In order to minimize this artifact, patient restraint is required. Physical restraint of the avian patient for radiography is rarely adequate. Proper positioning of the awake patient is difficult. There is

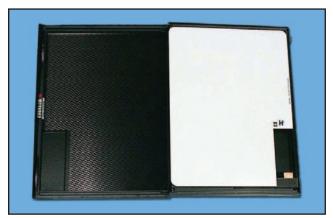

Fig 25.1 | Mammography cassette^a opened to reveal the single intensifying screen.

Fig 25.2 | Mammography film^b has a single-sided emulsion. When loading cassettes, the light side of the film should be in contact with the white side of the cassette.

significant stress and risk of injury to the bird, as well as increased risk of radiation exposure for the handler. Restraint in the form of inhalant anesthesia (isoflurane or sevoflurane) is strongly recommended. The risk of general anesthesia should be assessed for each patient, but usually this risk is far outweighed by the benefits of decreased patient stress, increased quality of the radiographs, less time spent by staff, less exposure to radiation and fewer patient injuries.

Respiratory motion is largely unaffected by appropriate planes of anesthesia. Avian respiratory rates require relatively short exposure times to eliminate the motion artifact. In practice, exposures of 0.01 to 0.05 seconds are routinely used.

Other machine settings also influence radiograph quality. Selection of a smaller focal spot setting, if available, will result in sharper edge definition. Increases in the focal spot-to-film distance will positively affect detail; however, the mAs (milliamperes seconds) or the kVp (kilovolt peak) also must increase proportionately. A compromise focal spot-to-film distance of 40 inches (100 cm) is often used.

Scatter radiation adversely affects the detail of radiographs. This is particularly true when high-detail or mammography screens are used. Close collimation of the primary beam around the areas of interest is important to decrease scatter. Birds are routinely positioned with the film cassette on the tabletop. This decreases the object-to-film distance and maximizes detail. Grids are useful to decrease scatter radiation when the thickness of the object being imaged is greater than 4 inches (10 cm); however, few birds are thicker than this so grids are rarely used.

Film-screen combinations contribute significantly to image quality and exposure settings. A "faster" film will have larger silver halide crystals. The larger size of these

crystals makes them more likely to be exposed to x-rays or light, thus they require a lower exposure to produce an image. However, the image will be less sharp than the same image made on a "slower" film with smaller crystals and a higher exposure. Intensifying screens are generally made of rare-earth crystals that fluoresce when struck by x-rays. Mammography cassettes^a and film^b offer an excellent combination for high-detail radiographs. The initial cost of the screens is higher, but used screens are often available at discounted prices through human imaging centers. Mammography film is more expensive than standard radiographic film. Mammography cassettes have screens on only one side and mammography film is single-sided emulsion. Proper loading of the cassettes is essential. The dark side of the film faces the dark side of the cassette and the light side faces the light side (Figs 25.1, 25.2). Most automatic processors can routinely develop these films, though their non-standard size may create problems in some models. Mammography film is often still damp after the drying cycle as programmed into most automatic processors. Care should be taken to avoid damage to the developed film and to provide for additional drying time. It also is important to realize that mammography cassettes require a higher exposure setting than typical doublescreened cassettes (Table 25.1). Non-screen film such as dental radiography film also provides excellent detail and requires higher exposure settings.

Table 25.1 | Technique Chart Used for Psittacines in the Author's Practice Using Mammography Cassettes^a and Film^b

Species	mA	Time (in sec)	kVp (kilovolt peak)
Budgerigar	300	1/10	40
Cockatiel	300	1/10	41-42
Pionus/mini macaw	300	1/10	43
Amazon/African grey	300	1/10	45
Large cockatoo/macaw	300	1/10	48-50

Fig 25.3 | Routine positioning of an anesthetized bird for the ventrodorsal projection.

Fig 25.4 | Routine positioning of an anesthetized bird for the laterolateral projection.

POSITIONING

The principles of positioning the avian patient for radiography are the same as for other species. At least two views, 90° to each other, are suggested. Positioning may be maintained by taping the patient directly to the cassette or to a radiolucent Plexiglas board. Masking tape is usually sufficient in the chemically immobilized patient and has the advantage of not pulling out feathers when it is removed.

The basic views of the body are the laterolateral and the ventrodorsal (Figs 25.3, 25.4). When assessing positioning for the laterolateral view, the two femoral heads should overlie one another, the legs should be pulled caudally, the sternum should be parallel to the film and the wings should be secured dorsally. In the ventrodorsal view, the legs should be pulled caudally. Wings are stretched and secured laterally, and the sternum should directly overlie the vertebral column.

Standard views of the wing are the ventrodorsal (positioned as for the body) and the caudocranial view. The legs are evaluated with routine orthogonal lateral and anterior/posterior views.

Skull radiography is challenging due to overlap of multiple structures, and their complex relationships. In order to optimize interpretation of these films, lateral, ventrodorsal and oblique projections are suggested.¹⁵

Radiography of the skull is indicated for evaluation of bony structures, including identification of fractures, luxations, hyper- and hypocalcemia, and carcinoma.⁸ Sinuses and soft tissue structures may be visualized, but changes

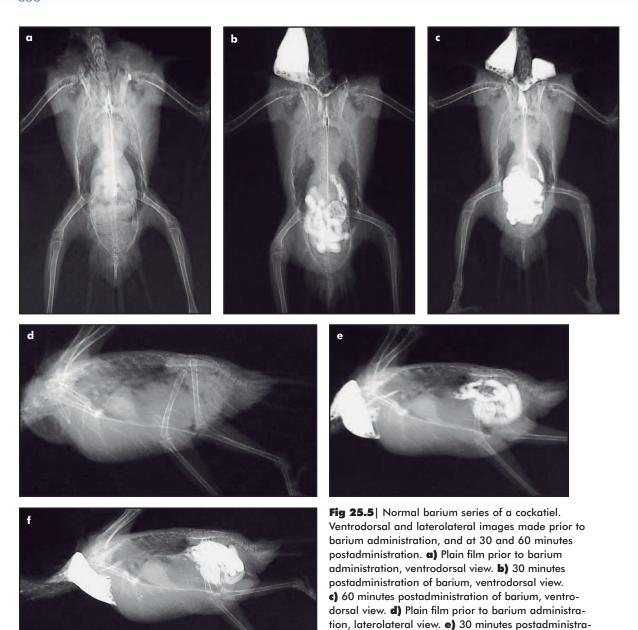

in these structures tend to be visible only in advanced stages of disease. Magnetic resonance imaging (MRI) is a more sensitive tool for evaluation of these structures. ¹⁶

The standard oblique views are left 75° ventral-right dorsal and right 75° ventral-left dorsal. The lateral view is obtained with the bird positioned in lateral recumbency with the neck extended. Foam wedges are used to support the skull such that the sagittal plane of the skull is parallel to the film. For the ventrodorsal view, the patient is placed in dorsal recumbency with the neck hyperextended such that the hard palate is parallel to the cassette. Tape is used to secure the beak to the cassette. Additional views may be required on a case-by-case basis. Endotracheal tubes may interfere with interpretation of skull views, especially the ventrodorsal. If pathology is suspected, the endotracheal tube can be removed and an additional radiograph obtained.

GASTROINTESTINAL CONTRAST STUDIES

Contrast studies of the upper and lower gastrointestinal (GI) tract are often indicated based on suspicion of space-occupying masses, ulceration, abnormalities in size or shape of coelomic organs, GI foreign bodies, alterations in GI motility or body wall abnormalities (Figs 25.5a-f).

Thirty percent weight to volume barium sulfate suspension is the most commonly used contrast medium. Approximately 25 ml/kg given by gavage tube into the crop is the suggested guideline. Iohexol^c (240 mg iodine/ml) diluted 1:1 with tap water also may be used

at 25 to 30 ml/kg.4

A preliminary study comparing GI transit time of psittacines restrained manually to those chemically restrained with isoflurane revealed no significant differences between the two groups. Regardless of the type of restraint used, great care should be taken to avoid contrast aspiration, especially in the early stages of the study when the crop is distended. Precautions include avoiding external pressure on the crop, maintaining the head in a slightly elevated position and intubation of anesthetized birds.

The use of iohexol^c results in significantly decreased GI transit time.⁴ The crop-to-cloaca transit time of barium is

approximately 3 hours, compared to approximately 1 hour with iohexol. If barium is used, films are made at 5, 30, 60, 90, 120 and 180 minutes or possibly longer. A slightly different schedule of 1, 3, 15, 30, 60 and possibly 120 minutes is recommended if iohexol is used. Iohexol also eliminates concerns of contrast material residue if endoscopy or surgery is indicated. If perforation is suspected or possible, iodinated contrast should be used.

tion of barium, laterolateral view. 1) 60 minutes post-

administration of barium, laterolateral view.

Retrograde or cloacally administered barium may be useful in detection of cloacal or colonic abnormalities such as ulcerations or masses. Caution should be used to avoid barium entering the oviduct or ureters.

Ultrasound

Ultrasonography uses the transmission and reflection of sound waves to produce an image. Organ visualization in the avian patient is limited when compared to mammalian species, as the ultrasound waves cannot penetrate the gas-filled air sac system. However, there are several applications for use of ultrasonography in the avian patient.

Due to the small size of most birds and the limited windows of accessibility, the ultrasound transducer must have a small contact area or footprint. Sector transducers, producing a wedge-shaped image, are appropriate as they tend to be smaller than linear transducers and allow good maneuverability. Their disadvantage is a smaller field of view compared to a linear transducer. This is of minimal consequence when dealing with the small avian patient. A transducer frequency of 7.5 MHz or higher is recommended.⁹

There are three acoustic windows to the coelomic viscera of the avian patient: (1) the cranioventral approach, on midline just caudal to the sternum; (2) the caudoventral approach, between the pubic bones; and (3) the lateral approach, in the flank area directly behind the last rib on each side. Based on the size of the bird and the size of the transducer, not all of these windows may be accessible in each patient.

While not always necessary, patients ideally should be fasted for 2 to 4 hours prior to examination. Food and gas within the gastrointestinal tract may impede visualization of other organs. Birds are restrained in dorsal recumbency, with the head and cranial coelom elevated with a 30° foam wedge to assist in visualization. Feathers are either parted or plucked and wetted with a small amount of isopropyl alcohol. Acoustic coupling gel is applied to the skin to provide adequate contact between the transducer and the skin. In the non-pathologic state, liver, heart and active gonads (usually the ovaries) are distinguishable. Spleen, normal kidneys and inactive gonads are difficult to identify.9

The indications for ultrasound include investigation of superficial soft tissue masses, hepatomegaly, cardiac disease, renomegaly, disorders of the reproductive tract and identification of ascites.

Hepatomegaly is commonly diagnosed with conventional radiography. The normal liver should not extend caudal to the sternum and has a characteristic coarse, homogeneous echotexture similar to the mammalian liver. Hepatic disease can be focal or diffuse. The abnormal areas may be sampled by fine needle aspiration (FNA) or biopsy for definitive diagnosis. General anes-

thesia is recommended for both procedures.

Ultrasound-guided hepatic FNA is accomplished using a 22-gauge, 1-inch needle with a 6-inch extension set. A study comparing FNA sampling techniques found that collecting multiple parenchymal samples with the needle under 0.5 ml of suction produced the most high quality hepatic cells with the least hemodilution¹⁴. In this study of 27 normal Amazon parrots, no morbidity or mortality was associated with hepatic FNA. Percutaneous ultrasound-guided hepatic biopsies may be obtained using a 20-gauge Trucut needle. The depth of the biopsy will vary with the size of the bird.

Echocardiography in the avian patient is in its early stages. The heart is usually visualized cranial to the liver via the cranioventral acoustic window. Standardized imaging planes and chamber sizes have yet to be established. Endocarditis, pericardial effusion, valvular insufficiency and cardiomyopathies may be diagnosed using mammalian criteria as a guide (see Chapter 12, Evaluating and Treating the Cardiovascular System).

The normal kidneys are not visible during ultrasound examination due to their anatomic position within bony depressions of the pelvis and the surrounding abdominal air sacs. Nephromegaly may be detected if the kidneys extend beyond normal landmarks, as described in radiographs discussed above, and can be characterized as focal or diffuse. Ultrasound-guided renal biopsy has not been reported.

Inactive gonads are not generally identified on ultrasonographic examination. Active or enlarged gonadal tissue can be evaluated with ultrasound. In the male, testes enlarged due to seasonal, neoplastic or inflammatory conditions may be identified. A study of the normal sonographic appearance of the reproductive tract of 52 hens of various species identified 17 of 34 (50%) active ovaries, all in hens greater than 70 g body weight.9 Active ovaries were characterized by the presence of follicles in various states of development. Follicles are initially round with indistinct anechoic or hypoechoic inner structure. As development advances, the more echogenic yolk is visualized. The ovarian parenchyma, identified between follicles, has higher echogenicity and a non-homogeneous appearance due to the presence of rudimentary follicles. As ova progress through the magnum, they exhibit distinct separation of echogenic yolk surrounded by anechoic albumen. The hyperechoic shell is added in the uterus and is easily distinguishable. The shell prevents further examination of the inner structures of the egg. Cysts of the ovary are visualized as clearly defined, rounded, anechoic structures within the parenchyma. Cysts may occur singly or in multiples.

Ultrasonographic examination is particularly valuable in cases of suspected egg binding. Thin-shelled, non-shelled, malformed and fully shelled eggs can be identified. Mineralized eggs are visible as round to oval structures of varying echogenicities resembling onion layers. They are surrounded by anechoic to hypoechoic fluid. Concurrent salpingitis should be suspected when oviduct walls appear thickened. The inflammatory exudate in the lumen of the oviduct may be anechoic to hypoechoic (see Chapter 18, Evaluating and Treating the Reproductive System).

Computed Tomography

Computed tomography (CT) is a cross-sectional imaging modality that uses x-rays to create a digital image or slice (Fig 25.6). that can be reformatted into additional planes of view.² Image densities are similar to conventional radiographs. The cross-sectional image eliminates overlying structures so objects of interest are more accurately visualized. CT is best suited for evaluation of bone and air-filled structures. Soft tissue resolution is inferior to MRI (see below). Reports of the use of CT include examination of the skull, sinuses and the lower respiratory tract.^{1,6,8,10} Machines vary in acquisition time and width of slice. Typically, the study can be performed in less than 10 minutes. General anesthesia is required for the study.

Magnetic Resonance Imaging

A review of the physics of magnetic resonance imaging (MRI) is beyond the scope of this chapter. Simplistically, a strong external magnetic force is used to align certain atoms within the body about a desired axis. The field is then turned off and the unit senses energy released as atoms return to their resting state.² The image produced is cross-sectional.

MRI is particularly useful for imaging soft tissue structures including the brain, spinal cord, coelomic organs and the upper respiratory tract. This MRI modality has been evaluated in the diagnosis and management of chronic sinusitis in psittacines. ^{16,17} In contrast to conventional skull radiography, where identification of disease was limited to osseous changes or changes in pneumatization, MRI was successful in the identification of caseous plugs, granulomas, a mucocele and a polyp. ¹⁶ The accurate localization of these lesions within the sinuses permitted the planning of an optimal surgical approach and drain placement for treatment.

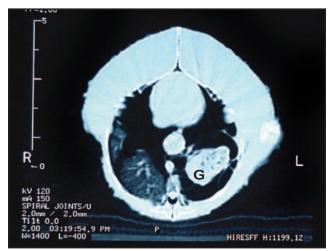

Fig 25.6 | Computed tomography image of a transverse slice through the coelom of an Amazon parrot at the level of the lungs. The right lung is normal. The normal architecture of the left lung is replaced by a cystic mass that was diagnosed as a foreign-body-associated granuloma (G) on histopathologic examination. The heart, keel and normal pectoral musculature are visible toward the top of the image.

Advances in the technology of MRI have decreased the time required for image acquisition, though general anesthesia is routinely required. MRI studies usually take a longer period of time to preform than CT studies. The decreasing cost and increasing availability of this imaging modality will increase its usefulness in avian diagnostics.

Myelography

Techniques for myelography in avian patients have been described. Indications include evaluation of the spinal cord for compressive, traumatic or space-occupying lesions. MRI should be strongly considered as an alternative if feasible. In larger patients (1 kg and greater), a 25-gauge needle is placed at the thoraco-synsacral junction and 0.8 to 1.2 ml/kg of non-ionic iodinated contrast medium is injected into the subarachnoid space (see Chapter 17, Evaluating and Treating the Nervous System).

Excretory Urography

Excretory urography (EU) is indicated for identification of renal mass lesions, ureteral obstruction and abnormalities in renal excretion. The use of sodium diatrizoate (680 mg I/kg), iothalamate sodium (800 mg I/kg), and meglumine diatrizoate (800 mg I/kg) has been reported without adverse effects. ¹² Contrast agents are warmed to body temperature prior to intravenous administration, and radiographs are made at 1, 2, 5, 10 and 20 minutes. The technique has been described in

further detail.¹² The absence of a renal pelvis and physiologic variations in avian renal function limit the usefulness of this procedure in birds. See Chapter 16, Evaluating and Treating the Kidneys for further considerations and alternate contrast agent doses.

Diagnostic Value of

Necropsy

MADELINE A. RAE, BS, DVM, MS, Dipl ABVP-Avian

Gross necropsy and postmortem diagnostic testing are important parts of avian medicine, requiring a systematic approach to the examination of organs and the collection of samples.

Necropsy examination functions as more than a way to satisfy the curiosity of the client, breeder or attending veterinarian — it provides important information that can be used in the diagnosis and treatment of future cases. Clinical signs and clinical pathologic findings are often not definitively explained until necropsy.

Postmortem information can be invaluable in educating clients regarding the seriousness of husbandry, nutritional and infectious disease conditions, thereby preventing them from making the same mistakes with subsequent birds. For grieving owners, necropsy findings can relieve them of some or all of the guilt associated with the death of a beloved pet.

Necropsy findings are an integral part of the flock database from which husbandry, management, treatment, vaccination and quarantine recommendations can be made.

In situations where the client may be dissatisfied with treatment or outcomes, it is wise to have a veterinary pathologist perform the necropsy. Developing a relationship with a veterinary pathologist is also highly recommended so that appropriate samples are submitted, optimizing the chances of arriving at a diagnosis. The veterinary pathologist should have training, experience and interest in companion and free-ranging birds.

Preparing for the Necropsy

The supplies needed for an avian necropsy are listed in Table 26.1. Although bottles or jars of neutral buffered 10% formalin should be available for the collection of specimens for histopathology, some cautions are in order. Ensure that formalin fumes do not contact tissues that are to be cultured for bacteria or viruses, as this can compromise the culture accuracy. Make certain that formalin fumes do not come in contact with blood or tissue cytological smears, as this can severely distort staining and interpretation.

A standardized necropsy form should be used and diagnostic specimen accession forms and instructions should be readily located. All specimen containers should be clearly labeled with the appropriate information. A refrigerator, a freezer, insulated shipping containers and coolant packs should be available for appropriate handling and shipping of specimens. After the necropsy has been performed, the carcass can be frozen and saved for a period of time, as frozen tissues may be useful if initial testing is inconclusive. Have arrangements in place for appropriate disposal of carcasses and infectious wastes.

Table 26.1 | Supplies Needed for Avian Necropsy

- Gram scale
- Apron
- Mask
- Gloves Disinfectant
- Necropsy checklist
- · Scalpel handle and blades
- Scissors*
- Thumb forceps*
- Small rongeurs or toenail nippers for brain removal and bone cutting
- · Ophthalmic scissors and forceps for small passerines, neonate and dead-in-shell
- · Sturdy paper plates and/or plastic cutting board
- · Microscope slides and coverslips
- · Blood and fluid collection tubes
- Sterile saline
- Sterile culturettes (aerobic and anaerobic)
- Sterile cotton-tipped applicators
- · Magnifying head loupe
- · Good light source
- Sterile sealable plastic bags or sterile plastic vials for sample collection
- Plastic screw-top jars containing 10% neutral buffered formalin
- Sterile syringes and needles
- · Stains (Gram's, Wright's, Giemsa or Diff-Quik, acid-fast)
- Butane lighter or other heat source to heat-fix smears for acid-fast staining

*Autoclave one set of scissors and forceps for collecting samples aseptically.

METHOD OF EUTHANASIA

In some instances, it may be appropriate to euthanize a sick bird in order to diagnose a flock problem. The method of euthanasia is important to consider because many injectable agents can cause severe artifacts in tissues. If at all possible, barbiturates should not be injected into the coelomic cavity, thoracic cavity or heart. The barbiturates are very acidic and crystals readily precipitate, causing severe tissue destruction that may obscure gross and histologic lesions. Even intravenous barbiturate solutions can cause intravascular erythrocyte lysis and some tissue damage as the solution pools within blood-filled organs.

Gas anesthetic agents seem to provide the least amount of tissue artifact (less muscle contraction artifact, no cell lysis). Once the gas agents anesthetize the bird, there is the opportunity to collect antemortem blood samples for hematology, serum chemistries, hemoparasite detection, serology and toxicology. The gas anesthetic agents can then be followed with intravenous euthanasia agents, if needed, and the amount of injectable agent necessary is usually quite reduced.

PREPARING THE BODY

The necropsy should be performed as soon after death as is possible. In order to prevent dry feathers from insulating the body and delaying cooling, wet the feathers with a detergent and water solution. The detergent and water also decreases the dispersal of feather and fecal dust into the local environment, thereby decreasing the transmission of infectious agents.

The body should be refrigerated, not frozen. Freezing can create artifacts in the tissues that may seriously obscure histologic lesions. Postmortem autolysis also can obscure histologic lesions, so if necropsy cannot be performed within 3 days, the body should be frozen, realizing that histopathology is likely to be compromised.

When shipping a cooled body, be sure the ice packs (or other frozen coolants) do not directly touch the body as this may freeze the body tissues, especially in very small birds. Wrap the ice packs in bubble wrap or newspaper to prevent freeze damage.

GUIDELINES FOR OBTAINING THE HISTORY

A detailed history should be obtained, just as the clinician would do upon seeing a live bird for the first time in the examination room (Table 26.2) (see also Chapter 6, Maximizing Information from the Physical Examination).

Table 26.2 | Considerations for Obtaining History Information

- Start with the age of the bird and sex, if known. Breeders are often very interested in having the sex of the dead bird confirmed at necropsy. If the dead bird is from a pair that is known to have produced fertile eggs, the knowledge of the mate can be deduced from the confirmation of the dead bird's sex. The breeder then knows which sex of bird to replace in the pair.
- Determine what the bird's purpose is, whether it is a dear pet, a display bird or a breeder bird.
- It is important to obtain a detailed description of the diet fed, and for how long, including any supplements and grit, brands used and their storage.
 Keeping a stored sample frozen in an airtight container may be useful.
 Quality control by the manufacturer and storage of formulated diets can be a problem. The resulting products may be over-formulated or rancid, resulting in toxic levels over time.
- Determine if there have been changes

- in appetite and/or droppings.
- How is water provided and how often is it changed?
- Have feeding practices or the diet changed recently?
- If this is a chick that is being hand-fed, obtain a detailed description of the feeding practices, brand of food with amounts and times per day, as well as any charts documenting weight loss or gain.
- Is the bird allowed to fly freely within the house?
- Ask for a description of the cage and its placement within the house (eg, near the kitchen where exposure to toxic fumes may occur).
- Is bedding material used and how often is the cage cleaned? What products are used for cleaning?
- Are there toys in the cage and does or can the bird chew on them?
- If this bird is from an aviary, a description of the aviary and floor plan can be very helpful.

- How many other birds are in the home or aviary and how many have died in the last year? Are any other birds in the household or aviary ill? Was the deceased bird in quarantine? Are any humans in contact with the ill birds?
- Have there been any recent changes in environmental conditions such as temperature changes?
- Have there been recent additions to the aviary or household?
- Ask about the reproductive history of the bird, such as a recent history of egg laying, dystocia or feeding of chicks
- Obtain a description of recent clinical signs noticed prior to death and their duration.
- Ask about any other previous illnesses or conditions. Were any medications or treatments given to the bird? Be sure to ask about prescription medications as well as over-the-counter preparations.

PREVENTING CONTAMINATION

Perform the necropsy in a well-lighted, well-ventilated area (preferably under a fume hood), and wear gloves, a mask and, if possible, a disposable apron. Aerosols from feathers, feces and exudates can be infectious. This is particularly important with cases of chlamydophilosis and mycobacteriosis, which can be zoonotic. However, it also is important to contain the feather dander and feces in cases of avian polyomavirus and psittacine circovirus infections, so as not to contaminate the premises, your clothing or other adjacent birds.

Disinfectant solutions should be readily available for clean-up after the necropsy, but neither these solutions nor their fumes should come in contact with tissues being collected, as they may lyse cells and destroy microorganisms needed for culture.

Step-by-Step Necropsy Procedure

The particular routine used for gross necropsy of birds can vary, but what remains the same is that all organs and systems are examined, and the use of a checklist will ensure this. Use the Necropsy Checklist (Table 26.3) to document all findings, both normal and abnormal. Make this checklist a part of the medical record and send a copy to the veterinary pathologist with any fixed tissues.

It is important to collect samples of everything (all organs, the grossly normal and abnormal). Labeling sealable bags and formalin jars prior to the necropsy with the owner's name and the tissues enclosed can save time and prevent interruptions in the flow of the necropsy.

After the necropsy is completed, the decision of which samples to send and what tests to request can be made, and at the very least, the diagnosis will not be cremated with the carcass.

EXTERNAL EXAMINATION

The necropsy begins with an external examination. Record the band number and scan for microchips; these can be removed, labeled and saved as proof of identification. Weigh the bird using a gram scale and record the weight on the checklist. Palpate for obvious fractures; radiographs may be warranted in some instances.

Examine the skin and feathers: often, feather abnormalities may not be visible while the feather remains in the follicle. For example, the concentric pinching of the feather shaft, seen in psittacine circovirus infection, may not be visualized until the feather is plucked from the follicle. Look for stress bars in the wing and tail primaries (Fig 26.1). Collect multiple blood feathers, both plucked and in the follicle, along with any skin lesions (Fig 26.2) and place them in formalin. Check for any signs of

trauma or bruising. In neonates, closely examine the umbilicus for cleanliness and the adequacy of healing.

Examine the unfeathered portions of the legs and the feet for poxvirus lesions, bumblefoot, herpesvirus pododermatitis and self-mutilation (Figs 26.3, 26.4). Examine the uropygial gland, found at the base of the tail in some species, and collect it for histopathologic evaluation, as this can be a site of chronic inflammation and neoplasia.

Evaluate the beak, both the external and the intraoral surfaces (Fig 26.5). Open the mouth. Look at and under the tongue for abnormalities. Look in the choanal slit for mucus and exudate and for blunting of the choanal papillae (Fig 26.6). Salivary gland enlargement can occur at the base of the tongue and can be due to hypovitaminosis A, bacterial abscesses or, rarely, mycobacterial infections.

The nares and ear canals should be clear and free of

debris or exudate. Examine the conjunctivae and the nictitating membranes. In Columbiformes, these tissues can be collected for *Chlamydophila* diagnostics, as they may contain elementary bodies.

The infraorbital sinuses should be opened as aseptically as possible, and swabs or aspirates collected for cytology and culture of bacteria, *Mycoplasma* and fungi (Figs 26.7, 26.8). Bacterial sinusitis is quite common in psittacines, but also occurs in passerine species, and caseous exudate is often seen (Fig 26.9).

In cockatiels (*Nymphicus bollandicus*) with "lockjaw," sinusitis and temporomandibulitis are common, as well as myositis of the mandibular muscles. The mandible and its attached muscles can be placed in formalin for histopathology. In these cases, bacteria such as *Bordetella avium*, *Enterococcus*, *Escherichia coli* and *Enterobacter* may be isolated. It is important to indicate to the

Fig 26.1 | Dystrophic feathers from a sulfur-crested cockatoo (*Cacatua galerita*) infected with psittacine circovirus. Note the concentric pinching of the feather shafts.

bacteriology laboratory that *B. avium* is suspected because this organism is somewhat fastidious and colonies may take longer to appear. *Bordetella avium* also may cause tracheitis, bronchitis and pneumonia in cockatiels and rarely in other psittacines.

Several *Mycoplasma* species have been implicated in conjunctivitis and sinusitis in psittacines and passerines, but these require special media for isolation and are recovered uncommonly. In small passerines, cross-sections of the nasal cavity and sinuses can be submitted

Fig 26.2 | Dermal lymphosarcoma in a western screech owl (Otus kennicottii).

Fig 26.5 | Cutaneous pox involving the commissures of the mouth in a red-tailed hawk.

in formalin, decalcified if needed, and examined histologically. Sometimes the nasal cavity epithelium may be the only site of viral inclusions diagnostic for canarypox. Cryptosporidial rhinitis and conjunctivitis also can be diagnosed with this method.

COELOMIC CAVITY

The coelomic cavity examination is begun by placing the body in dorsal recumbency, incising the skin of the abdomen and peeling it back caudally over the abdomen

Fig 26.6 | Normal choanal slit of a bluefronted Amazon parrot (Amazona aestiva). Choanal slit (A), caudal palate containing salivary glands (B), choanal papillae (P), palatine beak (C).

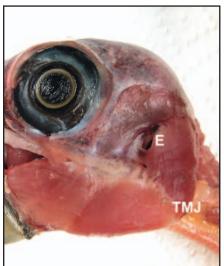

Fig 26.7 | View of the avian skull with the lateral wall of the infraorbital sinuses cut away in a blue-fronted Amazon parrot. Exudate may accumulate in the temporomandibular joint (TMJ), especially in cockatiels. Ear (E).

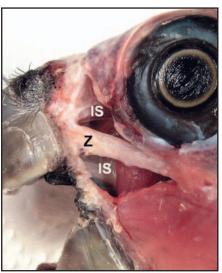

Fig 26.8 | View of the infraorbital sinuses in a blue-fronted Amazon parrot with the lateral wall removed. Infraorbital sinuses (IS), zygomatic or jugal arch (Z).

and cranially over the pectoral muscle mass. Assess the condition of the pectoral muscle, as this is a good measure of weight loss (Fig 26.10). Notice whether subcutaneous fat is present or absent and whether there is any bruising or edema. Grasp the sternum with thumb forceps and slightly elevate, maintaining tension on the abdominal wall. Make a transverse incision with the scalpel blade just caudal to the edge of sternum, being careful not to lacerate the liver. Remove the keel and pectoral muscles in one piece by cutting through the ribs and shoulder girdle with scissors or rongeurs.

Liver and Spleen

Assess the size, color and consistency of the liver. Hepatic margins should be sharp and not extend beyond the caudal edge of the keel in an adult bird (Figs 26.11-26.13). Note whether a gall bladder is present or absent, as not all species have one. Assess the condition of the air sacs and coelomic surfaces that are visible. If coelomic fluid is present, collect it with a sterile syringe for analysis. Aseptically collect samples of air sacs next, since they are delicate structures that readily disappear with further manipulation of the organs. Aseptically collect liver samples: one sample each for bacteriology, virus isolation or DNA probe testing, *Chlamydophila* testing and histopathology, and use any remaining tissue for toxicology and/or impression smears.

Grasp the ventriculus, elevate and incise through the attached membrane/air sac along the left margin and rotate the ventriculus counterclockwise to find the spleen. The spleen is nestled in the curve between the proven-

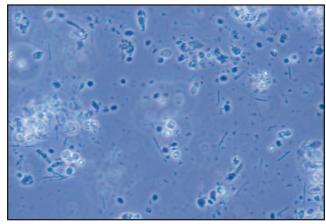

Fig 26.9 | Spirochetes in a wet mount of exudate from the infraorbital sinuses of a cockatiel chick (*Nymphicus hollandicus*), photographed under phase contrast.

triculus and the ventriculus (Fig 26.14). Evaluate the size and shape of the spleen. Determining whether it is of normal size for the bird being necropsied requires some practice, so measuring the diameter can be helpful. The spleen is round in some species, such as Psittaciformes and Galliformes, and elongated or sock-like in Passeriformes and Columbiformes. Note the color and the presence of any pale foci in the spleen. Collect the entire spleen, dividing it into three samples: one for virology, one for *Chlamydophila* diagnostics and one for histopathology. The spleen is the single most important sample for the histopathologic diagnosis of avian polyomavirus infection, since this is where viral inclusions are

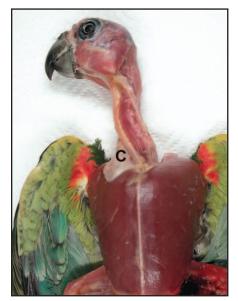

Fig 26.10 | View of the normal pectoral muscles of a blue-fronted Amazon parrot following removal of the skin. Crop (C).

Fig 26.11 | The liver extends beyond the caudal edge of the keel, indicating hepatomegaly in this mature red-tailed hawk with multiple mycobacterial granulomas in the liver.

Fig 26.12 | Marked hepatomegaly in a Lady Gouldian finch (*Chloebia gouldiae*). In this case, the hepatomegaly was due to lymphosarcoma, but a number of diseases can cause marked hepatomegaly in passerines.

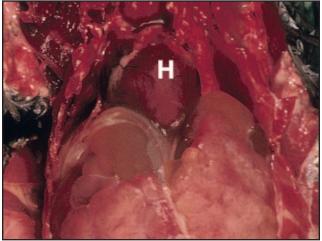

Fig 26.13 | Cholangiocarcinoma in an Amazon parrot (Amazona sp.). This tumor can have a very pleomorphic gross appearance. Heart (H).

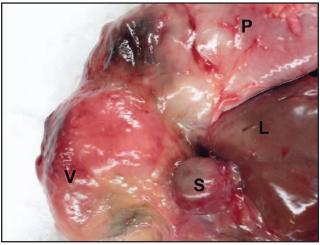

Fig 26.14 | Normal spleen in a blue-fronted Amazon parrot. Spleen (S), liver (L), proventriculus (P), ventriculus (V).

Genitourinary

Reflect the ventriculus and the intestinal tract to the right side of the bird to view the adrenals, gonads and kidneys, leaving the unopened gastrointestinal tract for last to avoid contamination of the other abdominal organs. The adrenals are often obscured by active gonadal tissue, so it is easier to collect the cranial division of the kidney with the adrenal and gonad(s) attached for histopathology. Adrenalitis is sometimes noted in unexplained death and may be the only abnormality in some psittacines with proventricular dilatation disease (PDD).

Sex the bird visually. In most species, only the left ovary and oviduct develop in females, but both testes develop in male birds. The gonads may be pigmented (brown or black) in some species, most notably cockatoos. Note the degree of development of the ovary and oviduct. Is there follicular development? If so, record the general size of the follicles. Is the oviduct hypertrophied?

Open the oviduct to look for exudate and tumors, and collect samples for bacteriology and histopathology as needed. Neoplasms of the oviduct may occur in the mucosa or myometrium. Testicular tumors are common in budgerigars (*Melopsittacus undulatus*) and ducks (Fig 26.15), but seasonal testicular enlargement also occurs. In some species, such as in many passerines, this enlargement can be mistaken for neoplasia; histopathology can usually distinguish between these two changes.

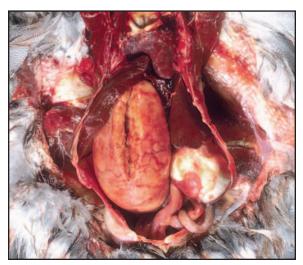

Fig 26.15 | Seminoma of the testes in a mallard duck (Anas platyrhynchos).

The kidneys are nestled in the renal fossae of the synsacrum, with the lumbosacral plexus lying deep to the caudal divisions of the kidney bilaterally (Fig 26.16). The ureters run down the ventral surface of the kidneys. In addition to the kidney/adrenal/gonad tissue collected as described above for histopathology, aseptically collect additional renal samples for virology, toxicology and bacteriology (if exudate is present).

In small birds (under 30 g), one can make an en bloc excision of the kidneys still in situ within the synsacrum and place this in formalin. After fixation, renal dissection is easier and/or the synsacrum can be decalcified and cross-sections of kidney together with bone can be cut. After removal of the kidneys, evaluate the lumbosacral plexus, especially in cases of pelvic limb weakness or malfunction. Samples of these nerves can be collected in formalin for histopathologic evaluation.

THORACIC INLET

Move to the thoracic inlet region. Identify the thyroids and parathyroids, located cranial to the heart and adjacent to the carotid arteries bilaterally, and collect them for histopathology (Fig 26.17). Goitrous changes were once quite common in budgerigars, but are less so with the advent of commercial diets. Hyperplastic goiter has been reported in juvenile macaws recently, but the cause is currently unknown. Lymphocytic thyroiditis also may be seen histologically, especially in Amazon parrots (Amazona spp.). Thyroid tumors are uncommon, but seem to be observed most often in cockatiels, where they tend to be very vascular.

Normal parathyroids are barely visible. When they are prominent, metabolic bone disease should be consid-

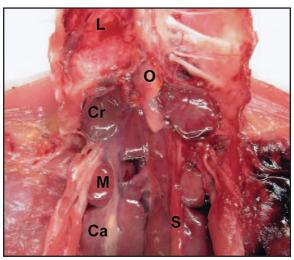

Fig 26.16 | Dissection displaying kidneys, reproductive structures and lung from a normal blue-fronted Amazon parrot. Lung (L), ovary, immature (O), cranial division (Cr), middle division (M) caudal division (Ca) of the kidney, salpinx or oviduct (S).

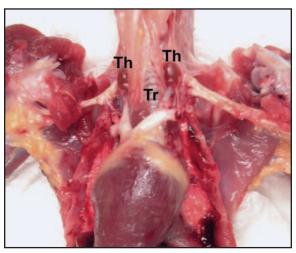

Fig 26.17 | View of the thoracic inlet, thorax and cranial abdomen following removal of the keel and pectoral muscles of a blue-fronted Amazon parrot. Thyroids (Th) are located cranial to the heart on either side of the trachea (Tr), close to the carotid arteries. The parathyroids are located at the caudal margin of the thyroids and are barely visible in normal birds.

ered. Parathyroid hypertrophy is usually the only gross pathologic lesion found in the hypocalcemia syndrome of African grey parrots (*Psittacus erithacus*).

In young birds, multiple pale lobules of thymic tissue can be found along the cervical region, from the jaw to the thoracic inlet (Figs 26.18, 26.19). Thymic tissue can be collected for virology and histopathology. Thymomas occasionally are seen as circumscribed, fairly encapsulated masses; they tend to be slow growing, undergoing cystic degeneration with large areas of hemorrhage. Thymic tissue is usually quite difficult to detect in adult birds.

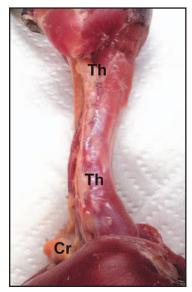

Fig 26.18 | Left lateral view of the neck of a normal young bluefronted Amazon parrot revealing multiple lobules of thymic tissue along its entire length from the jaw to the thoracic inlet. Thymus (Th), crop (Cr).

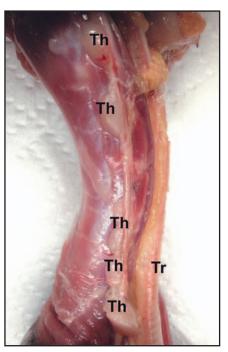

Fig 26.19 | Right lateral view of the neck of a young blue-fronted Amazon parrot revealing multiple lobules of thymic tissue along its entire length from the jaw to the thoracic inlet. Thymus (Th), trachea (Tr).

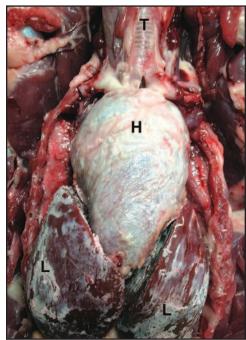

Fig 26.20 | Visceral gout in a red-tailed hawk with severe deposition of urates in the pericardial sac and in the perihepatic membranes. This is a very important gross lesion for the practitioner to recognize, because the urates may dissolve out of the tissue when placed in formalin. A smear of the white material can be examined under polarized light to reveal the typical urate crystal structure. Trachea (T), liver (L), heart (H).

Cardiac

Examine the heart, pericardium and great vessels. Visceral gout can cause the deposition of white, mucoid urate material in the pericardial sac (Fig 26.20). View a smear of this material under polarized light to confirm the presence of uric acid crystals. It is very important to recognize the gross appearance of visceral gout, because formalin fixation may dissolve the uric acid crystals and they may not be visible on histopathology (crystals do not dissolve if fixed in ethanol, but this is usually not a practical fixative for other reasons).

Suppurative pericarditis can be caused by a variety of bacteria such as *Pasteurella* and *Chlamydophila*. Cytologic examination of the pericardial exudate may reveal the causative organisms. Portions of the pericardial sac can be included in the tissues used for *Chlamydophila* diagnostics. Hydropericardium is a common finding in avian polyomavirus infection in juvenile psittacines.

Prior to removing the heart from the thoracic cavity, heart blood can be collected using a sterile syringe and needle for bacteriology. Smears of heart blood can be stained with Wright's stain and examined for hemoprotozoa and microfilaria, or Gram's stained to look for bacteria. Cardiomyopathy, usually the dilative form, can occur in birds. The cause of the cardiomyopathy is often obscure by the time it becomes a clinical problem, but myocardial degeneration and fibrosis are often seen histologically. After removing the heart and great vessels, open the heart in the direction of blood flow, using water to rinse away blood and clots. (See Chapter 12, Evaluating and Treating the Cardiovascular System for measurements of the heart). Look for thrombi, valvular endocarditis lesions and pale areas in the myocardium. Congenital cardiac anomalies are rarely diagnosed.

Open the great vessels to look for atherosclerosis, which may involve the aorta, pulmonary artery or carotids. Atherosclerosis is characterized grossly by yellowish, raised, intimal plaques, but occasionally may be so severe that the carotids are completely obstructed. Mineralization of the great vessels also may occur in association with atherosclerosis or may be related to renal disease and hypervitaminosis D.

Atherosclerosis is most commonly seen in African grey parrots, where it can be mild to moderate, but also in obese, older Amazon parrots, older macaw species (*Ara* spp.) and captive raptors, where it can be so severe that it results in acute death (Fig 26.21). Atherosclerotic

Fig 26.21 | Atherosclerotic plaques on the luminal surfaces of the great vessels of the heart in an Amazon parrot (Amazona sp.). Note the smooth, glistening luminal surfaces of the normal heart on the left.

lesions also may be found in the coronary arteries, but usually these lesions are discovered upon histopathologic examination. Atherosclerosis is a commonly missed diagnosis because the vessels are not opened and examined.

It is best to place most of the heart in formalin so that multiple sections can be cut for histopathologic evaluation. Pale foci or streaks can indicate degenerative myopathy related to vitamin E/selenium deficiency, or myocarditis associated with septicemia or viral diseases such as West Nile virus or PDD. Petechial and ecchymotic epicardial hemorrhages are commonly seen in cases of acute death from avian polyomavirus.

Lungs

Examine the lungs in situ prior to removing them. Avian lungs are fixed in place within the avian thoracic cavity and are not freely moveable. Removal requires gentle teasing of the lung tissue away from the ribs. The avian lung is one tissue in which gross lesions may appear quite significant, but upon histopathologic evaluation turn out to be just passive congestion. Conversely, grossly normal lungs may contain significant histologic lesions. So, it is wise to always include lung for histopathology, even if it appears grossly normal. Collect a portion of the lung for bacteriology and virology and place the rest in formalin for histopathology. Because lesions can be focal or multifocal, it is best to include a large portion of at least one lung for histopathology.

In canaries and mynahs, a Wright's-stained impression smear of lung (along with impressions from liver and spleen) is very important in detecting the monocytic form of atoxoplasmosis, as Atoxoplasma organisms are not usually visible on histopathology. Sarcocystis organisms, bacteria and fungi also can be seen in impression smears of the lung.

ORAL CAVITY AND GASTROINTESTINAL TRACT

Cutting through the mandible at one of the lateral commissures allows access to the caudal pharynx and visualization of the glottis (Figs 26.22, 26.23). The larynx and trachea can then be opened down to the tracheal bifurcation, looking for hemorrhage, exudate, foreign bodies, granulomas, and parasites such as respiratory mites or Syngamus nematodes. Laryngeal papillomatosis can occur in the pharynx and may occlude the glottis (Fig 26.24).

Tissue samples should be collected for histopathology and virus isolation, as well as bacteriology and fungal culture if warranted. Fungal tracheitis, especially at the syrinx, can be diagnosed by cytologic examination of exudate or granulomatous material, fungal culture and/or by histopathology. Rarely, mycobacterial organisms can cause syringeal granulomas.

In canaries, Enterococcus faecalis can cause chronic tracheobronchitis; culture of the tracheal lumen is necessary for diagnosis. Viral tracheitis is rare in psittacine birds, but a herpesviral tracheitis, bronchitis and airsacculitis have been reported in Neophema parrots. Canarypox can produce a severe tracheobronchitis with intracytoplasmic inclusions. A severe, chronic tracheobronchitis can be seen with Bordetella avium in cockatiels: this organism also is often associated with the "lockjaw" syndrome of sinusitis and temporomandibulitis.

Esophagus and Crop

Going back to the pharynx, the cut can extend downward the length of the esophagus and into the crop, looking for lacerations, punctures, peri-esophageal abscesses and other abnormalities. In game birds, the esophagus and crop may exhibit moderate to marked thickening and mucus production due to capillariasis. A wet mount scraping from the crop can reveal the typical bipolar capillarid ova. In juvenile psittacines, thickening and "Turkish towel" appearance of the crop mucosa is often due to candidiasis, and either a wet mount smear, cytology or Gram's stain of a crop mucosal scraping can be diagnostic (Fig 26.25).

Trichomonads can be found in wet mounts from the oral cavity and/or crop of Columbiformes and raptors, but also may occasionally be found in the crops of budgerigars and passerines. The crop contents can be collected in a plastic bag and frozen, if there is any suggestion of toxin ingestion. A large section of crop, to include a large vessel and adjacent nerve, should be collected for histopathology, since PDD lesions are often closely associated with the nerves.

Fig 26.22 | Cutting through the mandible allows opening of the entire oral cavity and better visualization in a blue-fronted Amazon parrot.

Fig 26.23 | Normal glottis from a blue-fronted Amazon parrot. Tongue (T), glottis (G).

Fig 26.24 | The glottis of this lilac-crowned Amazon parrot (Amazona finschi) is occluded by laryngeal papillomatosis.

Fig 26.25 | Severe crop mycosis in a cockatiel chick.

At this point, the esophagus distal to the crop can be transected. Caudal traction of the distal esophagus and sharp dissection of the mesenteric attachments can be utilized to remove the entire gastrointestinal tract.

Bursa of Fabricius

Continue the dissection to make a circular incision around the vent, leaving a margin of intact vent skin and the bursa of Fabricius attached to the tract. The bursa is present in young birds usually less than 6 to 12 months of age and is located dorsal to the cloaca. The bursa should always be collected when it is present and divided in half. Submit one half in formalin for histopathology and save the other half for virology and/or DNA probe testing.

The bursa is important in diagnosing psittacine circovirus, especially in young African grey parrots that die acutely without feather lesions, since the bursa may be the only site where viral inclusions are found. Circoviral inclusions also can be found in the bursa of young pigeon squabs dying from a variety of secondary infections. Lesions in the bursa are often non-specific as to etiology, but can indicate the acuteness or chronicity of stress.

Proventriculus and Ventriculus

Open the distal esophagus with scissors, continuing on into the proventriculus and ventriculus. Evaluate the stomach contents for amount and any foreign material. Washing the contents into a bowl or strainer can allow the food material to be rinsed away, leaving metallic and other foreign bodies behind. Collect and freeze the contents for possible toxicologic analysis. Rinse the mucosa with water and make wet mount and dried smears of mucus and/or mucosal scrapings. Do not separate the proventriculus and ventriculus.

The isthmus (the junction between the proventriculus and ventriculus) is a common site for avian gastric yeast (formerly known as megabacteria); its suggested new name is *Macrorbabdus ornithogaster* (see Chapter 30, Implications of *Macrorbabdus* in Clinical Disorders) (Fig 26.26). Grey-cheeked parakeets (*Brotogeris pyrrhopterus*) seem to be prone to the development of gastric carcinoma at the isthmus and the gross lesions are often unexciting. Collect a large specimen of proventriculus, isthmus and ventriculus (all in one piece if possible), containing at least one large serosal nerve and blood vessel, for histopathology.

In small birds, the entire proventriculus and ventriculus can be placed in formalin. A large specimen

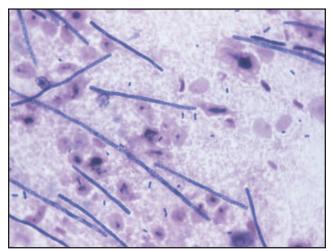

Fig 26.26 | Large gram-positive organisms consistent with the yeast Macrorhabdus ornithogaster (formerly known as megabacteria) are seen in a Gram's-stained smear of intestinal contents from a cockatiel. Note the size difference between these fungal organisms and the smaller gram-positive bacilli.

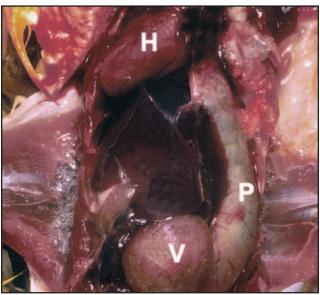

Fig 26.27 | Marked dilatation of the proventriculus (P) in a macaw (Ara ararauna) with proventricular dilatation disease (PDD). H= heart, V= ventriculus.

allows multiple sections to be examined by the veterinary pathologist in the search for nerves and plexi. Dilatation of the proventriculus and/or ventriculus is a hallmark gross lesion of PDD, but in juvenile psittacines being hand-fed, these organs also may be dilated as a normal finding. Histopathology is required to differentiate between PDD and normal juvenile underdevelopment of the proventriculus and ventriculus (Fig 26.27).

Foreign body penetration of the ventricular wall can occur in any species, but is most common in waterfowl and ratites. Nutritional muscular dystrophy (degenerative myopathy) can be seen in some species as white streaks in the ventricular muscle as a manifestation of vitamin E/selenium deficiency. Endoventricular mycosis (fungal invasion of the koilin lining of the ventriculus) can be seen histologically and is a common finding in debilitated passerines, despite the usually unremarkable gross appearance.

Duodenum and Pancreas

Open the outflow tract from the ventriculus and proceed into the duodenal loop. The largest limb of the pancreas lies in the duodenal loop mesentery while the small splenic lobe of the pancreas is located adjacent to the spleen. Pancreatic lesions are fairly common histologically, but gross lesions may not be very striking. The pancreas also is one of the first organs to undergo postmortem autolysis.

Quaker parrots (Myiopsitta monachus) are prone to the development of acute pancreatic necrosis of unknown etiology. Fat necrosis and serositis may accompany pancreatitis and pancreatic necrosis. Quaker parrots that survive the initial insult may develop severe pancreatic atrophy and fibrosis. Inclusion body pancreatitis can be seen with herpesvirus and adenovirus infections. Lymphoplasmacytic pancreatitis in Neophema parrots is associated with paramyxovirus infection. Pancreatic necrosis also is a common lesion in West Nile virus infection.

Vacuolar changes and necrosis of acinar cells may be seen in zinc toxicosis, but these lesions can be readily obscured by even mild postmortem autolysis. The pancreas concentrates zinc in the acinar cells and should be collected for toxicologic analysis, along with liver and kidney, to diagnose zinc toxicity. Collect a sample of pancreas for virology. Also submit in formalin a transverse section through the duodenal loop with pancreas attached, as this helps to identify the duodenum.

Yolk Sac

In neonate, the yolk sac and stalk should be evaluated for the degree of absorption. In psittacine and passerine chicks, the yolk sac is usually quite tiny by 3 days after hatching. Collect a sterile sample of the yolk material for culture and place the rest of the yolk sac (wall and contents) into formalin. Yolk sacculitis and yolk sac retention are common problems in neonatal ratites.

Intestines

Continue opening the intestine through the jejunum and ileum to the ceca (if present in the species) and colon. Collect sections of intestine for histopathology. Opened intestinal sections are usually best, as this gives the mucosa a chance to fix rapidly (Fig 26.28). Do not disturb the mucosa by scraping or handling, as artifacts

Fig 26.28 | Intestinal volvulus in an ostrich (Struthio camelus).

can confuse or obliterate the histologic diagnosis.

Wet mounts of intestinal contents (usually two different sites) are helpful in diagnosing parasitic and bacterial problems. Wet mounts should be examined for parasite ova and oocysts, as well as flagellates, yeast and motile bacteria. Sections of bowel can be tied off with string or suture and submitted for culture. In some cases, both aerobic and anaerobic culture may be warranted (Fig 26.29).

If necrotic lesions are encountered in the intestinal mucosa, clostridial disease should be considered. Quail disease caused by Clostridium colinum is a common problem in quail, and typical "button ulcers" can be seen in the intestines as well as "crateriform" necrotic lesions in the liver. Clostridial enteritis, usually caused by Clostridium perfringens, is becoming more commonly recognized in psittacines, especially nectar eaters such as lories and lorikeets. Clostridial organisms in large numbers can cause acute necrohemorrhagic enteritis. Finding large gram-positive bacilli, with or without spore formation, as the primary organism on a Gram'sstained smear of intestinal contents gives a presumptive diagnosis that should be followed by anaerobic culture (Fig 26.30). Because exposure to oxygen in the air can inhibit clostridia, it is wise to tie off a loop of unopened, affected bowel with string or suture and place it in a sealable bag with the air evacuated prior to sending it for anaerobic culture.

A wide variety of other bacteria can cause enteritis and septicemia. Gram-negative organisms, especially Entero-

Fig 26.29 | Fibrino-suppurative enteritis in a tufted puffin (Fratercula cirrhata).

bacteriaceae, are common infectious agents in psittacines and passerines. In addition, *Campylobacter* spp. and *Yersinia pseudotuberculosis* are more common in canaries and exotic finches. *Campylobacter* organisms usually require special media and microaerophilic incubation conditions, so it is wise to alert the bacteriology laboratory when this organism is suspected.

Multifocal granulomas or thickened areas of bowel can be indicative of mycobacteriosis. These sites should be collected for histopathology, and special acid-fast tissue stains can be applied to paraffin sections to demonstrate the organisms. Alternatively, impressions or scrapings from these sites can be stained with a rapid acid-fast stain for a quick, presumptive diagnosis. Sections of affected bowel can be collected for mycobacterial culture.

Intestinal neoplasia is fortunately uncommon in birds, but needs to be included in the differential diagnosis of thickened or proliferative bowel lesions.

Flagellate protozoa and coccidial organisms also may produce enteritis. Flagellates (including *Giardia* spp. and *Cochlosoma* spp.) are diagnosed by fresh wet mount smears of intestinal contents, but they are nearly impossible to diagnose on histopathology. Coccidiosis can be diagnosed by wet mount smears of intestinal scrapings and by histopathology. Nematode and cestode parasites are uncommon in domestically raised psittacines and passerines, but geographic pockets of these parasites may exist and should always be considered (Fig 26.31). These parasites are still common in ground-feeding and feral or wild birds.

Ceca

Many species of birds do not possess ceca. Psittacines do not. Passerines and Columbiformes have tiny vestigial ceca composed of lymphoid tissue, while Galliformes, Anseriformes and ratites possess large bilateral ceca.

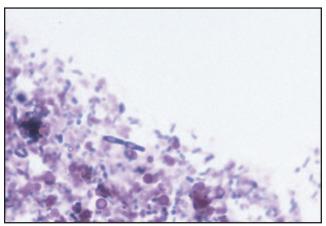

Fig 26.30 | A Gram's-stained smear of intestinal contents from a lory (Trichoglossus haematodus) that died of acute necrohemorrhagic enteritis. Clostridium perfringens was isolated from the intestinal tract. Note the large gram-positive rods with subterminal spores.

These should be opened to look for cecal worms and their contents should be included for culture. Cecal contents should be included in culture for Salmonella, especially in Galliformes.

Colon

Colon contents should start to look like fecal material as one moves toward the cloaca. Open the cloaca to look for papillomatous lesions, cloacoliths, trauma, inflammatory lesions and neoplasia (Fig 26.32).

In summary, intestinal samples should include the following: wet mounts from at least two different sites, smears for Gram's stain and possibly acid-fast stain, contents for aerobic and possibly anaerobic bacteria or Campylobacter culture, tissue for histopathology and ingesta for virology (direct electromicroscopy, virus isolation and/or DNA probes), and toxicology.

NEUROLOGIC

The brain and spinal cord can be very important in the diagnosis of some diseases, especially PDD. The dorsal calvarium should be carefully removed with rongeurs (Fig 26.33). Visualize the brain in situ for any obvious abnormalities such as abscesses, which should be cultured. Remove the brain by inverting the skull and transecting the ventral and cranial attachments (Fig 26.34). Collect a portion of the forebrain for virology and toxicology, and fix the rest of the brain in formalin. In neonates, the brain is so soft that making a cut through the dorsal skull and placing the entire calvarium containing the brain in situ into formalin is recommended. After fixation, the brain will harden somewhat and it can be removed more easily without damaging it.

A similar procedure can be followed for the cervical

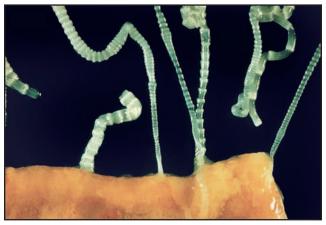

Fig 26.31 | Tapeworms attached to the intestinal mucosa of a great horned owl (Bubo virginianus).

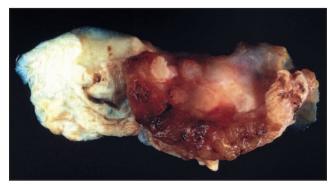

Fig 26.32 | Cloacal papillomatosis is seen in a lilac-crowned Amazon parrot. The cloaca has been opened caudally to cranially.

spinal cord. Cut the vertebral column with cord in situ into 2- to 3-cm pieces and fix in formalin overnight. This process will allow easier removal using rongeurs, with minimal damage to the less fragile, fixed spinal cord. In very small birds, cross-sections of the cervical vertebral column with the spinal cord in situ can be decalcified and examined histologically.

In birds with head tilt or neurologic disease, especially Neophema parrots and exotic finches, fix a large portion of the petrous temporal bone containing the middle ear. This bone can later be decalcified by the veterinary pathologist and sectioned to examine the middle ear for inflammation and viral inclusions associated with paramyxovirus infections. Congestion of the vascular sinuses in the bones of the skull is a common finding, but it is significant only if there also is corresponding subdural hemorrhage or bleeding of brain parenchyma.

The eyes can be removed and fixed in formalin if there is any suspicion of blindness, ocular or neurologic disease. Dissection through some orbital bone may be required for removal. Remember that the avian eye has bony scleral ossicles, which may make their sectioning somewhat more difficult. The globes can be transected at the optic nerves or dissection can be carried out

Fig 26.33 | View of the dorsal surface of calvarium of a psittacine bird with congested vascular sinuses (S).

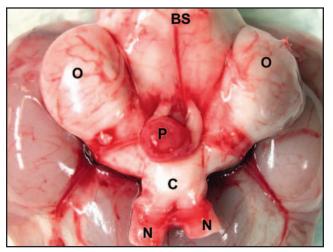

Fig 26.35 | View of the ventral surface of the brain from a blue-fronted Amazon parrot. Pituitary (P), optic lobes (O), brainstem (BS), optic chiasm (C), optic nerves (N).

Fig 26.34 | Dorsal surface of a normal brain from a blue-fronted Amazon parrot.

Fig 26.36 | A pituitary tumor in a budgerigar (*Melopsittacus undulatus*).

through the ventral calvarium to keep the optic nerves and chiasm intact and attached to the brain. On the ventral surface of the brain near the optic chiasm is the pituitary (Fig 26.35). Tumors of the pituitary have been reported in budgerigars and cockatiels (Fig 26.36).

MUSCULOSKELETAL

Bone marrow can be collected by aspiration of the femur and smears made and stained for cytologic evaluation. Collect a segment of femur using rongeurs and place it in formalin. Once fixed, the previously fragile bone marrow can be dissected out and examined histologically. Leukemic or aplastic processes can be diagnosed from bone marrow samples, and circovirus inclusions also may occasionally be seen histologically.

Samples of skeletal muscle should be collected for histopathology. Muscular lesions may include trauma, hemorrhage, degeneration, mineralization, and injection or vaccine site reactions. Myositis, degenerative myopathy and *Sarcocystis* infection can be diagnosed histologically (Fig 26.37). Open the joints of the pelvic and thoracic limbs and look for exudate; collect synovial fluid with a sterile syringe for bacterial and mycoplasmal culture, although exudate also can be caseous.

Articular gout can be diagnosed by examining the exudate on cytology or by histopathology. The lesions of degenerative joint disease, periarticular proliferation and proliferative synovitis are fairly common in the joints of the feet, but also may occur in the shoulder, stifle and hock. Any bone or joint lesions demonstrated radiographically should be opened and sampled for culture and histopathology (Fig 26.38).

The flexibility of bones (eg, tibiotarsus, ribs) can be used in the assessment of the adequacy of mineralization. The bones should break with an audible snap if mineralization is normal. The rachitic "rosary" at the costochondral or costovertebral junctions and deformation of the keel or other long bones are obvious lesions of metabolic

Fig 26.37 | Pale areas in skeletal muscle from an emu (Dromiceius novaehollandiae) with degenerative myopathy. The heart muscle appears grossly normal.

Fig 26.38 | A proliferative osteosarcoma involving the right leg and pelvis of a peach-faced lovebird (Agapornis roseicollis).

bone disease. Sections of bone, especially areas of the metaphyses and epiphyses, can be examined histologically for metabolic bone disease.

Ratites are prone to developing angular limb deformities. The "rubber rhea" syndrome is often due to hypophosphatemic rickets. Other ratite limb deformities can be multifactorial, but nutritional imbalances in calcium, phosphorus and vitamin D₂, growth rates and problems with substrates are often implicated. Flock problems with limb deformities in ratites can be investigated through feed/forage analysis and bone ash analysis.

SMALL BIRDS AND DEAD-IN-SHELL

Necropsy of very small birds and neonates (under 15 g) is challenging. One can open the coelomic cavity and thorax and fix the entire body in formalin; opening the ventriculus as well is recommended for best fixation. The veterinary pathologist can then carry out dissection. It is very difficult to get good fixation of tissues in birds weighing more than 20 g, so this technique should not be used for them.

Dead-in-shell and egg necropsies can be performed, but there are limited lesions and testing available. Open the egg as aseptically as possible at the air cell end. Collect samples aseptically for bacterial culture, virology and DNA probes. Assess gestational age and positioning of the embryo or chick. Then place the embryos and membranes in formalin. Histopathologic diagnosis is often limited by autolysis, since the eggs often remain in the incubator for a period of time after embryonic death. Histologic examination of the blastodisk can help determine if the eggs are truly infertile or whether early embryonic death occurred post-fertilization.

Ancillary Testing of Samples Collected at **Necropsy**

After the necropsy has been concluded, the remaining parts of the carcass can be placed in a sealable plastic bag and frozen until diagnostic testing has been completed. Examine wet mounts of intestinal contents and crop or oral cavity scrapings as quickly as possible inhouse for parasite ova, oocysts, motile flagellates, yeast and motile bacteria.

MICROBIOLOGY

Stain impression smears from organs and bone marrow, smears of exudate, or cells from fluid analysis with a Wright's stain and examine for cell types and microorganisms, including bacteria and fungi. If bacteria are seen on the cytologic preparations, a stained smear can be destained and restained with Gram's stain, or another smear can be stained. If macrophages with "ghost bacilli" are seen on the cytologic preparation, an acidfast stain is in order to attempt to demonstrate mycobacterial organisms.

A Gram's stain of the colonic contents can be performed in-house to provide a quick evaluation of the presence of abnormal bacterial populations, and then followed up with culture. This type of Gram's stain is especially important in detecting possible clostridial organisms, which would then prompt an anaerobic culture. Avian gastric yeast also can be detected in fecal smears or from scrapings of the isthmus stained with cytologic stains.

Composite Samples

A collection of liver, spleen and air sac can be submitted

for *Chlamydophila* diagnostics. A Gimenez or Macchiavello stain can be performed on impression smears of air sac, liver and spleen for the demonstration of elementary bodies. In Columbiformes, conjunctiva and nictitating membrane should be included, as elementary bodies may be confined to this location in these species. Fluorescent antibody and chlamydial culture may be available at certain laboratories, and some also can perform a DNA probe for *Chlamydophila* on a swab from the combined surfaces of liver, air sac and spleen.

Tissues, exudates or swabs can be submitted to diagnostic laboratories for bacterial, mycoplasmal or fungal culture as indicated. With the exception of samples for *Campylobacter*, which does not survive freezing well, these samples can often be frozen if not sent for culture immediately.

Special media is required for the culture of *Mycoplasma* spp. Alert the bacteriology laboratory if fastidious organisms such as *Campylobacter* spp. and *Bordetella avium* are of interest in the particular species or individual bird, as these organisms often require special media and incubation parameters. DNA probe testing for *Salmonella* spp. is available at some laboratories. An antibiotic sensitivity tailored to drugs used in pet avian species also can be requested if other birds on the premises are at risk.

Mycobacterial culture is required for accurate speciation of acid-fast organisms, and special media and handling are necessary. Once *Mycobacterium* isolates are grown on solid media, some laboratories are capable of speciating the organisms by the use of DNA probes and may offer antibiotic sensitivity testing for mycobacterial isolates.

Fungal culture may be requested in cases of suspected mycoses and is often required for accurate identification of the species involved. Antifungal sensitivity testing is available at specialized mycology laboratories.

A pool of parenchymal tissues (liver, spleen, air sac, lung, kidney, brain and bursa if present) and a separate pool of intestinal contents should be refrigerated or frozen for possible virus isolation or DNA probe testing. A combination swab from heart blood and the cut surfaces of liver, spleen, lung, kidney and bursa can be submitted for DNA probe testing for viruses such as psittacine circovirus and avian polyomavirus. Fluorescent antibody techniques on frozen sections of tissue may be available for certain viruses.

Polymerase chain reaction (PCR) tests are available for the detection of certain viruses, such as West Nile virus, on fresh or frozen tissues. It is important to contact the individual laboratory so the most appropriate tissues are submitted, as this can depend on the particular virus or antigen and upon the particular laboratory's technique.

PARASITOLOGY

Direct wet mounts of intestinal contents and crop or oral cavity scrapings prepared and examined at the time of necropsy are invaluable in the diagnosis of trichomoniasis in pigeons, raptors and budgerigars; cochlosomiasis in finches and canaries; and giardiasis in cockatiels and other psittacine and passerine species. Many of these organisms dry up easily, so examination should be performed promptly. Examination of these wet mounts under dark field or phase contrast, if available, may make the detection of flagellates and motile bacteria easier. Inoculating Diamond's media and submitting the media for incubation can attempt culture of some trichomonad parasites.

Microscopy of whole parasites such as nematodes, cestodes, flukes and acanthocephalans may provide morphology that can point to the classification of the parasites, plus characteristic ova may be visible within the helminths. An acid-fast or auramine stain can be performed on smears for the detection of *Cryptosporidium* oocysts, which can be found in the intestine, conjunctiva, nasal cavity or bursa.

A stained smear of the heart blood or lung impression can be examined for microfilaria and hematozoa such as *Plasmodium*, *Hemoproteus* and *Leucocytozoon*. Wright's-stained impression smears of lung, spleen and liver are especially important in canaries and finches for the diagnosis of the monocytic form of atoxoplasmosis, as these organisms may not be visible histologically.

Rarely, flagellates can be demonstrated in impression smears from the lung, trachea, sinus and conjunctiva, which are not readily visible histologically. Other protozoal parasites such as *Sarcocystis*, *Toxoplasma* and *Leucocytozoon* can be found in impression smears of organs.

HISTOPATHOLOGY

Select a group of formalin-fixed tissues with lesions or a group of tissues that commonly contain histologic lesions that could lead to diagnosis and submit them for histopathology. This commonly includes tissues such as liver, spleen, air sac, kidney, lung, trachea, heart, bursa, brain, duodenum/pancreas and proventriculus/ventriculus. Save the remaining formalin-fixed tissues in case the diagnosis is not made with the first set of tissues.

This second set of tissues may include spinal cord, bone marrow, nasal cavity, skin and feathers, bone and joint, middle and inner ear, eyes, tongue, skeletal muscle, thyroid, parathyroid, adrenal, esophagus, crop, jejunum,

ileum, colon, ceca, gall bladder, ovary, oviduct, testes, thymus, nerve (ischiatic, brachial plexus) and beak.

The veterinary pathologist may recommend special diagnostics such as stains for acid-fast organisms, fungi, bacteria, iron or copper, depending on what is seen on the routine hematoxylin- and eosin-stained sections. In special situations, tissues may be embedded in plastic so that electron microscopy can be performed. Direct electromicroscopy also can be performed on intestinal contents or tissue homogenates. In situ DNA hybridization techniques on paraffin-embedded tissues are available for certain viruses such as Pacheco's herpesvirus, adenovirus, avian polyomavirus, psittacine circovirus and paramyxovirus.

Immunohistochemical stains can detect certain antigens from bacteria, fungi, viruses and parasites in paraffinembedded tissues, and these techniques also can be utilized to detect some cell markers in the diagnosis of tumors. Gene sequencing of certain microorganisms (*Clostridium perfringens*, for example) in formalin-fixed, paraffin-embedded tissues is available at some diagnostic laboratories.

TOXICOLOGY

Toxicologic testing requires some idea of what toxin is being considered. This information often comes from the history and histopathologic findings. Contacting the toxicology laboratory is essential for submission of the most appropriate tissues and amounts.

The most common toxins tested for are heavy metals such as lead and zinc. Usually liver and kidney are required for this analysis, although zinc also accumulates in the pancreas preferentially. Heavy metals also can be detected in foreign bodies, water and feed. Copper accumulation in the livers of swans can be demonstrated qualitatively with special histologic stains for copper, but quantitative levels require toxicologic analysis.

Iron storage disease is most commonly seen in toucans, toucanettes, mynahs and birds of paradise; the condition is rare in psittacines, although there is emerging evidence that lories and lorikeets may be prone to iron accumulation. The special histologic stain, Perl's Prussian blue, can provide qualitative information about the amount of iron in the liver, but, again, quantitative levels are detected by toxicologic analysis.

Poisonous plants can be found in the digestive tract and submitted to a botanist or university botany department for identification. The plants or wood can be frozen until submission to prevent the breakdown of toxic principles. Ingestion of fertilized plants can result in nitrate toxicity, and samples of these plants can be analyzed for the amount of nitrates present.

Polytetrafluoroethylene (PTFE or non-stick coatings) and other toxic inhalation products are rarely detectable in tissues, and the diagnosis is usually made by a history of exposure, the presence of pulmonary edema and hemorrhage, and the exclusion of other causes of death. There is a wide variety of items commonly found in the household that can give off PTFE fumes, including non-stick cookware and appliances such as self-cleaning ovens and electric grills.

Birds also can be sensitive to other inhalants such as carbon dioxide, carbon monoxide and fumes from glues, resins, plastics and paints. Mycotoxins may be implicated in the case of multiple birds suffering liver damage. Aflatoxins can be detected in foodstuffs, but usually by the time chronic liver damage is evident, the offending foodstuff is often no longer available. In the case of acute toxicosis, samples of the feed should be frozen along with liver and kidney, pending further investigation. Contact the toxicology laboratory for specimen requirements and costs.

Update on

Chlamydophila psittaci

A Short Comment

THOMAS N. TULLY, JR, DVM, MS, Dipl ABVP-Avian, Dipl ECAMS

Fig 27.1 | A bird infected with *C. psittaci* organism may not have clinical signs. This condition can occur in small birds such as this blue budgerigar.

Fig 27.2 | This lutino cockatiel has the upper respiratory signs associated with avian chlamydiosis. The bird tested positive for the disease. Additional therapies may be needed to treat secondary infections that arise as a result of the primary disease.

Chlamydophila psittaci is a zoonotic intracellular bacterial organism that causes the diseases psittacosis in humans and avian chlamydiosis in avian species. Clinical signs often associated with a psittacosis (human) infection include generalized "flu-like" symptoms to more severe pneumonia and complicating health issues. Avian chlamydiosis will present as non-specific clinical signs in a companion bird patient (Fig 27.1). These non-specific signs can include ocular, nasal or conjunctival irritation and discharge, anorexia, depression, dehydration, bright green urates and diarrhea (Fig27.2). Many avian species have been diagnosed with *C. psittaci*, but it is the companion bird species where this disease is the greatest public health concern.

It is often difficult to confirm a diagnosis of avian chlamydiosis because of the intracellular life cycle of the organism, prophylactic treatment of patients with appropriate antibiotics but using inappropriate doses and treatment periods, and the periodic shedding of elementary bodies (the infectious form of the disease). The difficulty to confirm avian chlamydiosis cases encourages the veterinarian to use multiple testing methodologies. Testing methods that can be used either individually or preferably in combination include pathology, antibody testing (direct complement fixation and elementary-body agglutination) and antigen testing (enzyme-linked immunosorbent assay, immunofluorescent antibody tests, polymerase chain reaction amplification technology on choanal/cloacal swabs and blood). Prior to sample submission, the diagnostic laboratory should be contacted for recommendations on proper sample collection, labeling, packaging

and shipment of the sample material. A breakdown in sample handling or shipment delay can adversely affect the reliability of *C. psittaci* test results.

There are several treatment options available to treat suspected or confirmed avian chlamydiosis cases. The treatment options are based on doxycycline as the drug of choice and being administered in the most appropriate way for the patient(s) to receive a therapeutically effective dose for the duration of the 45-day treatment regimen. There have been recent advances in using doxycycline hyclate powder from opened capsules as a seed coating for budgerigars or mixing the powder in water for larger birds. Oral doxycycline (monohydrate or calcium) or intramuscular injections of specific formulations can be effective treating the individual bird or group of birds that will tolerate the stress of capture and drug administration on a regular basis.

Chlamydophila psittaci is a public health concern and can be a deadly, expensive disease within an aviary or to the individual companion bird. Although difficult to diagnose, avian chlamydiosis can be diagnosed and treated if there is an understanding of the available tests,

and the proper tests are used to confirm the presence of the disease. Early communication to a client about the ability of this organism to resist improper treatment and the consequences of discontinuing treatment will often lead to owner compliance with antibiotic administration. In hopes of protecting birds and bird owners in the future, research is currently being conducted to improve *C. psittaci* diagnostic testing and to develop a vaccine to protect birds from infection if exposed to the infectious elementary bodies.

See Chapter 1, Clinical Practice for location the compendium of psittacosis control from the CDC. See Chapter 21 Preventative Medicine and Screening for a review of diagnosis and preventive measures.

Implications of

Mycobacteria

in Clinical Disorders

CHRISTAL G. POLLOCK, DVM, Dipl ABVP-Avian

Avian mycobacteriosis is generally a disease of captive populations. In the past, most cases were believed to have been caused by *Mycobacterium avium* and *M. intracellulare*. More recently, however, the atypical organism, *M. genavense*, has emerged as a significant cause of disease. Although the incidence of disease is relatively rare, the potential for avian mycobacteriosis to spread to humans makes this subject pertinent for avian veterinarians. In this chapter, aspects of avian mycobacteriosis, including clinical presentation, therapeutic options, zoonotic potential and diagnostic tests with promising new molecular techniques such as deoxyribonucleic acid (DNA) probes, will be covered.

Mycobacterium spp.

Mycobacterium avium and *M. intracellulare* are frequently grouped together as the *Mycobacterium avium intracellulare* (MAI) complex or *Mycobacterium avium* complex (MAC). Twenty-eight seeknown serotypes of MAI exist. ⁵⁶ The more pathogenic serotypes 1, 2 and 3 belong to the *M. avium* group. ^{20,54} Serotypes 4 to 28 make up the *M. intracellulare* group, which is considered relatively avirulent. ^{31,56,77} Historically, these two species were considered the cause of avian tuberculosis, and they still play an important role in avian mycobacteriosis today.

The atypical organism, *Mycobacterium genavense*, is an important cause of mycobacteriosis, especially in companion birds. ^{38,40-42} In a recent survey of necropsied pet birds in Europe, *M. genavense* was the predominant mycobacterial species isolated. ⁴⁹ *Mycobacterium genavense* is a fastidious organism only recently identified. It is most closely related to *M. simiae* and was first isolated from immunosuppressed human patients. ^{10,19,84} Addi-

tional atypical mycobacteria isolated from companion birds in rare instances include *M. fortuitum*, *M. gordonae* and *M. nonchromogenicum*. ^{38,41,70,79}

There also are rare reports of disease caused by *Mycobacterium tuberculosis* or *M. bovis*. ⁸⁰ All avian species studied have been relatively resistant to *M. bovis*. ¹³ *Mycobacterium tuberculosis* has been reported only in companion parrot species. ^{29,36,77,80} There are no case reports, as yet, of *M. tuberculosis* in passerines or free-ranging psittacines. ^{13,48} Infection is probably secondary to close contact with infected humans. ^{31,48} *Mycobacterium tuberculosis* was cultured from a green-winged macaw (*Ara chloroptera*) 3 to 4 years after active tuberculosis was diagnosed in two human occupants of the household. ⁸⁵

Pathogenesis of Disease

SOURCE OF INFECTION

Mycobacterium is a ubiquitous environmental saprophyte most commonly found in soil with heavy fecal contamination or other organic debris.³¹ High levels of mycobacteria also might be found in surface water or in marshy, shaded areas.^{20,77} Although wild birds are a possible source of infection, they are probably not an important source of disease for captive birds.^{6,18,43,77} The prevalence of mycobacteriosis is low (usually <1%) in most free-ranging populations.²⁴

TRANSMISSION

Avian mycobacteriosis is usually transmitted by the ingestion or inhalation of soil or water contaminated by feces, or, less commonly, by urine. Raptors might become infected by ingesting infected prey. A mechanical arthropod vector is a rare mode of transmission. Vertical transmission also is possible, however, avian mycobacteriosis is generally associated with an immediate halt in reproductive activity.

Pathogenesis

The primary site of entry and initial colonization of mycobacteria is the intestine. Subclinical bacteremia quickly follows and the organism spreads to the liver through the portal circulation. The absence of lymph nodes in the bird then allows mycobacteria to spread hematogenously to distant parenchyma such as the spleen, bone marrow, skin and lungs.^{29,36,80}

Disturbance of contaminated surface water might lead to the inhalation of aerosolized mycobacteria and direct colonization of the respiratory tract. Focal skin disease probably occurs secondary to the inoculation of *Myco*-

bacterium spp. into mucosal or dermal lesions, or by the use of contaminated needles.^{36,83}

HOST IMMUNE RESPONSE

The presence of humeral antibodies does not appear to protect against the development of avian mycobacteriosis. ^{20,82} In the mammal, cell-mediated immunity is much more important, and this also may be true in the bird. Studies evaluating growing layer hens inoculated with *Mycobacterium butyricum* found that dietary linoleic acid may boost cell-mediated immunity.⁶⁹

Clinical Disease

INCIDENCE

The distribution of avian mycobacteriosis is worldwide, although most reports of disease are from northern hemisphere's temperate zones. The incidence of avian mycobacteriosis is reportedly uncommon in some countries, such as Japan. 49,68

SIGNALMENT

Adult birds, 3 to 10 years of age, are most frequently diagnosed with avian mycobacteriosis. ^{20,51,80} There is probably no gender predilection, although some reports suggest a slightly higher incidence of disease in the female bird. ^{42,77,80}

Avian mycobacteriosis has been reported in virtually all avian taxonomic orders, however, susceptibility varies (Table 28.1). The greatest incidence of disease has been in captive collections of waterfowl, parrots, songbirds, and ground-dwelling birds such as farmed ratites and small poultry flocks. Reports also are common in the wood pigeon (*Columba palumbus*) and free-ranging waterfowl. Orders Falconiformes and Gruiformes also are considered susceptible. 6.16,20,24,27,41,43,44,95,59,60,77,80

Species considered relatively resistant to avian mycobacteriosis include rooks (*Corvus frugilegus*), turtle doves (*Streptopelia risoria*), turkey (*Meleagridis* spp.) and guinea fowl (*Numida meleagris*). Although the flamingo formerly was considered fairly resistant to avian mycobacteriosis, an epidemic was reported in lesser flamingos (*Phoeniconaias minor*) in 1993. More than 18,500 birds died over a 3-month period. 45,77

CLINICAL PICTURE

There are three forms of avian mycobacteriosis, which have been historically described as classical, paratuberculous or diffuse disease. The most common form of disease in the avian patient involves granulomatous lesions

Table 28.1 | Species Highly Susceptible to Avian Mycobacteriosis^{1,6,12,16,17,22,24,27,29,39,41,43,44,46,49,59,60,62,75,77,80,86,87,88}

Order	Species
Anseriformes	White-winged wood duck (Aix sponsa) Sea ducks (Somateria fischeri, Clangula hyemalis, Melanitta spp.)
Columbiformes	Wood pigeon (Columba palumbus)
Falconiformes	
Galliformes	Partridge (Alectoris spp., Lerwa sp., Ammoperdix spp., Tetraogallus spp.) Pheasants (Phasianus colchicus) Quail (Coturnix japonica)
Gruiformes	Cranes (Grus spp., Balearica spp., Anthropoides spp.) Rails (Rallus spp., Laterallus jamaicensis) Gallinules (Porphyrula spp.) Coots (Fulica spp.)
Passeriformes	Canaries (Serinus canarius) Sparrows (Passer domesticus) Hooded siskin (Spinus sp.) Lady Gouldian (Chloebia gouldiae)
Psittaciformes	Amazon parrots (Amazona spp.) Amazona ochrocephala auropalliata, Amazona farinosa, Amazona aestiva Grey-cheeked parakeet (Brotogeris pyrrhopterus) Budgerigar (Melopsittacus undulatus) Horned parakeets (Eunymphicus cornutus) Pionus (Pionus sp.) Ring-necked parakeets (Psittacula)

Table 28.2 | Incidence of Granulomatous Lesions with Avian Mycobacteriosis 29

	Common	Usually Absent
Charadriiformes (gulls, shorebirds)	✓	
Ciconiiformes (bitterns, herons, egrets, ibises)	✓	
Cuculiformes (cuckoos)	✓	
Falconiformes (hawks, eagles, falcons)	✓	
Galliformes (fowl)	1	
Gruiformes (coots, cranes, rails)	1	
Piciformes (toucans)	1	
Strigiformes (owls)	1	
Anseriformes (waterfowl)		✓
Columbiformes (pigeons, doves)		✓
Coraciiformes (hornbills, kingfishers)		✓
Passeriformes (songbirds)		1
Psittaciformes (parrots)		1

Fig 28.1 | Granulomatous intestinal lesions in a mallard duck (Anas platyrhynchos) caused by Mycobacterium avium intracellulare.

Fig 28.2 | Multifocal granulomatous lesions in the liver of a sandhill crane (*Grus canadensis*) caused by *Mycobacterium* spp.

in the gastrointestinal tract (Fig 28.1) and liver (paratuberculous) (Fig 28.2). Classic avian mycobacteriosis is associated with tubercles in many organs such as the kidney, liver and spleen, while diffuse disease may be associated with diffuse enlargement of affected organs. ^{24,29,80}

Granulomatous lesions are common in birds of prey but rare in pigeons and doves, waterfowl and most parrots (Table 28.2).²⁹ Diffuse mycobacteriosis has been most commonly reported in Coraciiformes, such as the kingfisher (*Alcedo* spp.), and Passeriformes.^{32,61}

Granulomatous Intestinal Disease

Granulomatous intestinal or paratuberculous disease is associated with muscle wasting and emaciation. Initially the bird will display a good appetite, but anorexia later develops. The presentation of wasting with an increased appetite can lead to the incorrect presumptive diagnosis of proventricular dilatation disease. Additional non-specific signs of illness might include poor feather quality, lethargy, weakness and pallor.⁵¹ Chronic or intermittent diarrhea may also be observed.^{12,29,80}

Abdominal distension due to enlargement of the liver or small intestines also might be detected. Ascites is rare, although it has been reported in Canada geese (*Branta canadensis*), mute swans (*Cygnus olor*), tundra swans (*Cygnus columbianus*) and some parrots. ⁸⁶

Musculoskeletal Disease

Reports in the literature describe anywhere from 2 to 93% incidence of bony lesions in avian mycobacteriosis.

Fig 28.3 | Granulomatous nodules within the skin of a lovebird (Agapornis roseicollis) caused by Mycobacterium spp.

Fig 28.4 | An irregular, firm, fleshy mass in the choana of a blue-fronted Amazon parrot (Amazona aestiva) caused by Mycobacterium spp.

Acute or chronic lameness, which might be shifting leg in nature, may be observed due to granulomatous lesions in bones or joints. The carpometacarpal and elbow joints are most commonly involved, and skin overlying the affected joints might be thickened and ulcerated. 29,80

Respiratory Disease

Granulomas within the lungs or compression of air sacs secondary to hepatomegaly can lead to dyspnea or exercise intolerance. Additional signs of respiratory disease are rare with avian mycobacteriosis, although focal nodules have been reported within the infraorbital sinus, nares and syrinx.14,71,85

Skin Disease

Tubercle formation within the skin also is rare. Dermatitis, diffuse, non-pruritic thickening associated with xanthomatosis, as well as pale, soft, subcutaneous masses have been reported in association with avian mycobacteriosis (Fig 28.3).25,29,80

Ocular Lesions

Granulomatous lesions may be associated with the eyelids, nictitating membranes, retrobulbar tissue and pecten. 1,62,71,77,85 There also is one report of keratitis associated with avian mycobacteriosis.74

Miscellaneous Lesions

In rare reports, granulomas have been found within the oropharynx (Fig 28.4), larynx or external auditory canal. 1,29,85 Endocrine abnormalities such as reproductive failure might occur secondary to an infection in the adrenal glands, pancreas or gonads.80 Avian mycobacteriosis also might be associated with neurologic signs due to involvement of the spinal cord, brain or vertebral column.52,77,80

ANTEMORTEM DIAGNOSTICS

Antemortem diagnosis of mycobacteriosis is difficult due to the wide variety of possible clinical signs and physical examination findings. A strong index of suspicion for avian mycobacteriosis can be based on signalment, clinical findings consistent with disease, profound leukocytosis, organomegaly and the cytologic presence of acid-fast bacteria. Serologic techniques such as enzyme-linked immunosorbent assay (ELISA) also may prove helpful in selected cases and are described in the following section on serology. A definitive diagnosis of mycobacteriosis relies on histologic identification or culture of the organism. Molecular techniques, such as DNA probes and nucleic acid amplification, also are promising in the aid of diagnosing avian mycobacteriosis.

Minimum Database

Minimum database results are variable. The complete blood count might reveal a marked heterophilic leukocytosis, monocytosis, thrombocytosis and elevated fibrinogen. Chemistry panel results often are unremarkable, although liver enzymes may be mildly to moderately elevated, and albumin levels may be decreased. Early in the disease process, a polyclonal gammaglobulinopathy also might be detected.35,77,80

Imaging

Radiographic findings can include hepatosplenomegaly and dilation of intestinal loops with gas (Fig 28.5).80 Gastrointestinal contrast radiography may demonstrate a thickened and irregular small intestinal wall. Granulomas may be identified within the bones, lungs or coelom, however, these lesions are more difficult to identify in the bird, since they do not calcify as in mammals.77

Radiographic findings involving bone might include lysis and/or sclerosis consistent with osteomyelitis, osteophy-

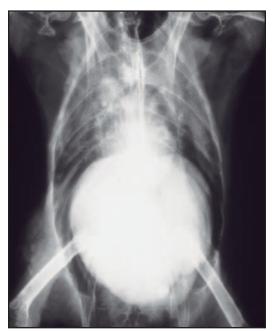

Fig 28.5 | Widening of the cardiohepatic silhouette on a V/D radiograph due to hepatomegaly caused by avian mycobacteriosis in an Amazon parrot (*Amazona* sp.).

tosis around arthritic joints, pathological fractures and endosteal bone densities.⁷⁷ Anatomic regions most commonly affected include the midshaft region of long bones, such as the humerus, tibiotarsus and ulna, and the ribs and sternum. There are rare reports of lesions involving the vertebrae and femur.⁸⁰ In an unusual case report, chondritis, osteitis and osteomyelitis were described in the nasal bone of a wood duck (*Aix sponsa*) with mycobacteriosis.²⁷

Ultrasonography and alternate imaging methods, such as computed tomography, also are potentially useful diagnostic modalities.

Laparoscopy

Laparoscopy is an extremely useful technique for identifying lesions on the serosal surface of the liver, spleen, intestine, lung and air sacs. Granulomas may be visualized as white, yellow or tan round masses, which are soft and easily biopsied.⁸⁰

Cytology

A large number of mycobacteria must be present (5 x 10⁴/ml) before the organism can be visualized microscopically; therefore, fecal acid-fast stains serve as a poor screening tool. The Ziehl-Neelsen stain is the standard method for identification of acid-fast organisms. A modified Ziehl-Neelsen stain utilizes peanut oil to reduce damage to the mycobacterial cell wall. Mycobacteria appear pink-red with the Ziehl-Neelsen stain. *Mycobacterium tuberculosis* is rod-shaped, while *M. avium* can appear almost coccoid or as long, beaded rods.^{3,77}

A suggestive diagnosis of avian mycobacteriosis may be based on identification of the organism in cytologic samples; however, the acid-fast stain is not a specific test, because non-pathogenic mycobacteria can be transient gastrointestinal inhabitants or environmental contaminants. Therefore, positive acid-fast cytology should be confirmed by culture, histopathology or DNA probe analysis.

Serology

Serologic tests available include hemagglutination (HA), complement fixation (CF) and ELISA. These tests are highly species-specific and they are available for only a limited number of species.

HA is a rapid, easy-to-perform assay run on whole blood or serum. The use of fresh whole blood might produce more sensitive (true positive) results than whole blood in EDTA or serum. Species-specific antigen is required for reliable results. HA has been of some use in waterfowl, domestic fowl, raptors and cranes.^{21,35}

ELISA is a sensitive, albeit labor-intensive, test that requires at least 24 hours before results are available. Highly species-specific antigen is required. For instance, a sensitive and specific ELISA exists for mycobacteria in feral barnacle geese (*Branta leucopsis*). ^{16,19,21,28,77}

CF titers of 1:20 or greater have been used to confirm infection or exposure to *Mycobacterium avium* infection in grey-cheeked parakeets (*Brotogeris pyrrhopterus*).⁵⁸

Culture

Culture has several practical limitations. *Mycobacterium* is only intermittently shed, and careful sample collection is necessary to prevent environmental contamination. Mycobacteria are difficult to culture, and no growth occurs even when proper protocols are followed. If growth does occur, at least 2 to 4 weeks are required for visible colonies to appear and up to 8 weeks of incubation is required. Some strains of *M. avium* require up to 6 months before colonies are identifiable.

Use of a radiometric culture method^a reduces the length of time needed for culture. This acidic culture medium is especially useful for isolation of the fastidious *Mycobacterium genavense*. In one study, only 3 out of 34 *M. genavense* isolates grew on conventional solid media, while the acidic culture medium supported growth of 23/34 isolates.^{41,43}

DNA Probes

The DNA probe assay is a rapid method for identifying various species of *Mycobacterium* grown in culture. Although a very sensitive (95%) and specific (100%) test,

the currently available gene probe^b is not sensitive enough to directly detect acid-fast bacilli in specimens.³

Polymerase Chain Reaction

Molecular techniques may be used to identify organisms grown not only on culture media but also identified within fecal, biopsy or necropsy samples, including formalin-fixed paraffin-embedded sections. ^{4,34,47} Polymerase chain reaction (PCR) methods^c, based on the amplification and sequencing of the small subunit 16S rRNA gene of mycobacteria, have been used to identify *M. avium*, *M. bovis* and *M. genavense*. ^{9,47,56,60,76}

One study comparing the sensitivity and specificity of various samples found that fecal specimens had the highest sensitivity by PCR (77.8%). Processing fecal specimens with the zwitterionic detergent, C₁₈-carboxypropylbetaine (CB-18), also might increase the sensitivity of test results.⁷⁸

Intradermal Skin Testing

Intradermal skin testing has been used for decades in poultry in the diagnosis of mycobacteriosis. A small volume (0.1 ml) of avian purified protein derivative tuberculin (PPD) is injected into the wattle or comb and assessed 48 to 72 hours later.^{7,55,77}

Unfortunately, intradermal testing has proven unreliable in a number of avian species including pigeons, geese, quail and raptors. In these species, intradermal skin testing is frequently associated with false negatives, especially in the early and late stages of disease. Testing has been attempted on skin over the hock, vent, wing web and eyelid. The skin just behind the ear also has been utilized in ratites.^{29,77}

POSTMORTEM DIAGNOSIS

Gross Findings

The gross necropsy findings of avian mycobacteriosis vary widely. Non-specific findings might include muscle wasting, loss of subcutaneous and intracoelomic fat and discolored, poor-quality feathers. There may be no significant gross findings in the diffuse form of mycobacteriosis. ^{59,80}

Organomegaly

Hepatosplenomegaly is one of the most consistent findings in songbirds and grey-cheeked parakeets (*Brotogeris* spp.) with mycobacteriosis. ^{11,63} Some birds may also demonstrate an enlarged, pale, firm liver due to amyloid deposition, which may eventually lead to hepatic rupture and hemorrhage. ⁷⁷ Polycystic livers and cystic granulomas have been reported in waterfowl. ⁶³

Intestinal Lesions

Distension or thickening of the intestines is an extremely common finding in granulomatous intestinal disease. Intestinal mucosa also may display a "shaggy carpet" appearance caused by prominently thickened or clubbed villi.⁷⁷ Proventricular lesions also may be identified.³⁷

Granulomas

Tubercles are frequently white, tan or yellow in color, and they might range in size from miliary foci to nodules several centimeters in diameter. Granulomas are most commonly located within the intestinal wall, liver, spleen and bone. ^{11,24,49,53,77} Granulomas also might be found in subcutaneous tissue as well as a variety of other viscera such as the kidney. ⁴⁶ Tubercle formation within the skin and lungs is rare. ^{25,29}

Miscellaneous Lesions

Additional lesions that might be identified with avian mycobacteriosis include the following: proliferative or lytic bony lesions (secondary pathologic fractures are possible),⁷⁷ dermatitis or diffuse thickening of the skin associated with xanthomatosis,⁸⁰ and pulmonary necrosis or ulceration.^{24,53} A single fluid-filled pulmonary cyst has been reported in a cockatoo.⁵⁷ An extremely unusual manifestation of mycobacteriosis was reported in fairy bluebirds (*Irena* spp.) with granulomatous cardiopulmonary arteritis.⁵⁰

Histologic Findings

The most common findings reported include granulomatous enteritis, splenitis or hepatitis with variable amounts of acid-fast bacteria. A marked accumulation of macrophages also may be identified within the dermis, mucous membranes and subserosa of the peritoneum and airsacs.²⁴ Granulomatous intestinal lesions can also be associated with expansion of the intestinal villi by diffuse granulomatous infiltrate and proliferations of epithelial cells within the glands of Lieberkuhn.^{29,83}

Large numbers of acid-fast rods are found in lesions caused by *Mycobacterium avium*, while *M. bovis* and *M. tuberculosis* tend to be found in relatively small numbers.⁸⁰

Granulomas generally do not possess a region of central calcification or an extensive necrotic center.⁸⁰ The necrotic regions that are identified in avian mycobacterial granulomas are surrounded by epithelioid cells, multinucleated giant cells and lymphocytes.^{38,53} Non-caseous granulomas may contain large macrophages with highly vacuolated cytoplasm and numerous acid-fast bacteria.⁶⁰

The diffuse form of avian mycobacteriosis is more difficult to recognize at necropsy, because organomegaly may not be observed. Instead, a diffuse infiltration with

large, foamy histiocytes may be seen. 23,32,61

THERAPEUTICS

Humane euthanasia is recommended for birds diagnosed with mycobacteriosis. Birds infected with *Mycobacterium avium* may continuously shed large numbers of organisms into the environment. ^{77,81} This potential zoonotic risk is especially important in households with immunosuppressed individuals, such as those on chemotherapy, the very young, the elderly and human immunodeficiency virus (HIV)-positive. Any humans in contact with an infected bird should consult a physician for evaluation.

Surgery

Surgical excision may be possible and perhaps even curative for discrete nodules in the skin, subcutaneous tissue or periocular tissue. Medical management is indicated for disseminated avian mycobacteriosis when treatment is deemed appropriate.

Medical Management

There are numerous drugs with anti-mycobacterial activity (Table 28.3). *Mycobacterium avium* isolated from human patients has been reported sensitive to azithromycin, clarithromycin, ciprofloxacin, rifabutin, rifampicin, amikacin, clofazimine and ethambutol. Doxycycline has shown efficacy against atypical mycobacterium like *M. fortuitum*.⁸¹

Multi-drug therapy should be employed in the treatment of avian mycobacteriosis. Numerous successful combinations have been reported in the literature (Table 28.4).^{8,65,66,75,81,82} Due to the intracellular nature of the pathogen, its slow growth, and the bacteriostatic activity of most anti-mycobacterial drugs, an extended course of treatment lasting 4 months or longer is recommended.

Immunotherapy has been a useful adjunct for treatment of human tuberculosis patients.^{72,73} Administration of killed *M. vaccae* has some immunomodulatory effects and has been associated with an improvement in sur-

Streptomycin or	20-40 mg/kg IM q 12 h			
	x 7-10d			

^{*}Lower doses have been reported

vival rates. *Mycobacterium vaccae* was used in a small trial in captive waterfowl; however, results were inconclusive.¹¹

CONTROL AND PREVENTION

Mycobacterium is extremely stable in the environment. It is highly resistant to environmental extremes and might

^{**}Drugs are mixed into a dextrose powder, then mixed into a small amount of food and given PO q 24 h.

survive for months or years in contaminated soil and surface water or less commonly in feed, feathers or discarded food.²⁴

There are no absolute means for control of avian tuberculosis. Quarantine and surveillance programs must strive to identify and eliminate infected animals. Providing complete, balanced nutrition and utilizing good sanitation practices will minimize the impact of disease. Stressors such as overcrowding also must be minimized.²⁶

Identification and Elimination of Infected Animals

The poultry industry has relied on the use of intradermal skin testing to identify and then eradicate affected birds. Unfortunately, this screening test has not proven useful in the exotic avian species studied to date. 30,40,51,77 In a zoological or aviary setting, an extended quarantine period of 3 to 6 months should be considered. 40,43 During this time, screening tests should include physical examination, hematology, serum biochemistry, acid-fast fecal smears and serology in those species for which it is available. Laparoscopy, fecal culture and PCR testing also should be considered.

If birds with confirmed mycobacteriosis are not euthanized, they must be kept permanently separated from other birds. Birds that were in contact with mycobacteria-positive individuals also should be quarantined for 1 to 2 years. During this time, periodic retesting every 6 to 12 weeks for mycobacteriosis is recommended.^{26,77}

Removal or Prevention of Tuberculosis in the Environment

To reduce the risk of exposure to mycobacteria, carefully consider cage design and sanitation. Prevent contact with wild birds. In aviaries or zoological collections, one should consider solid, non-porous flooring and other easily disinfected surfaces instead of dirt substrate. Footbaths should be utilized to minimize the potential introduction of mycobacteria into the enclosure.^{23,43}

Tuberculosis is more resistant to disinfectants than other non-spore-forming bacteria. To Compounds with antimy-

- Chemosterilizing gases -Ethylene oxide, Betapropiolactone

cobacterial activity include alcohol, aldehydes, halogens, peroxygens and phenols (Table 28.5).⁶⁷ The use of reed biofiltration systems to remove contamination from water also is being investigated.⁷⁷

Vaccination

There are only rare reports of vaccination against mycobacteriosis in birds. The bacille Calmette-Guérin (BCG) vaccine, a human product directed against *Mycobacterium tuberculosis*, was tried in poultry but was found to be of little benefit.³³ A vaccine against *Mycobacterium avium* also has been given to poultry and, more recently, captive waterfowl in Britain.^{54,64}

ZOONOTIC POTENTIAL OF AVIAN MYCOBACTERIOSIS

Are birds that live in close proximity to people a potential source of tuberculosis? Although the incidence of *M. avium* infection in human acquired immunodeficiency syndrome (AIDS) patients is increasing,⁴⁰ these mycobacterial strains are thought to be environmental in origin. Studies using DNA probes have shown that avian strains of *M. avium* rarely infect people.² Birds and humans are probably exposed to the same environmental sources of mycobacteria.³¹

CONCLUSION

Avian mycobacteriosis may be caused by MAI or atypical mycobacteria such as M. genavense. Birds usually are exposed to mycobacteria through soil or water contaminated by feces. Clinical disease varies with the species and strain of Mycobacterium spp., the species of bird affected and the route of transmission. Classically, however, mycobacteriosis is a disease of the gastrointestinal tract and liver in the bird. While identification of disease relies on intradermal skin testing in poultry, this has not proved useful in other avian species. Ancillary testing in nongallinaceous birds should include a complete blood count, imaging, laparoscopy, cytology, serology and PCR testing. A definitive diagnosis is based on culture or histopathology. Euthanasia is recommended for affected birds. Control should focus on identification of affected birds through quarantine and use of appropriate screening tests. Avoiding dirt flooring may reduce exposure to infectious material. Instead, utilize non-porous, easy-toclean surfaces, appropriate disinfectants and footbaths.

Implications of

Mycoses

in Clinical Disorders

ROBERT D. DAHLHAUSEN, DVM, MS

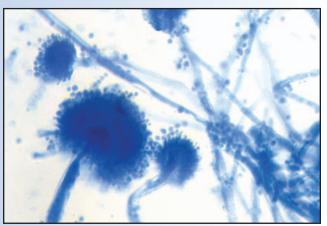

Fig 29.1 | New methylene blue stain of Aspergillus conidiophores from an air sac sample obtained at endoscopy.

Mycotic infections are relatively common in avian species. Many fungal agents exist in the environment as soil-borne saprophytes. Most birds are exposed to them in their normal habitat or aviary environment without effect. Nutritional disorders in parrots, stress of captivity in raptors and incubation-related disorders in hatchling galliforms, along with other causes of impaired immune function and environmental factors conducive to fungal proliferation, can cause disease to occur. Respiratory tract aspergillosis and alimentary tract infections due to Candida and other yeasts are the most frequent forms of fungal disease observed. The early diagnosis and successful management of systemic fungal disease can present a diagnostic and management challenge to the avian practitioner. Advances in diagnostic methods, improved knowledge of therapeutic agents and better management practices have reduced the morbidity and mortality associated with these agents.

Aspergillosis

Aspergillosis is a non-contagious, opportunistic infection referring to any disease condition caused by members of the fungal genus *Aspergillus*. The organism is an opportunistic, angio-invasive fungus that may act as an allergen, colonizer or invasive pathogen. It can produce both acute and chronic disease varying in spectrum from local involvement to systemic dissemination. It is the most frequent cause of respiratory disease and the most commonly diagnosed fungal disease in pet birds.⁷⁰ It also is considered the most common, non-traumatically-induced medical problem in free-ranging birds of prey.⁹² The disease is known to occur in a wide variety of captive and free-living birds. Almost all avian species should

be considered as potential hosts susceptible to *Aspergillus* infection.²

EPIDEMIOLOGY

Aspergillus spp. are ubiquitous fungi commonly found in nature in the environment, soil and feed grains. They are distributed worldwide and proliferate in environments with high humidity and warm (>25° C) temperatures. Moldy litter, grain and bedding material contaminated with feces are common media for fungal growth. Aspergillus fumigatus is the most commonly isolated species from birds with aspergillosis, followed by A. flavus and A. niger. Aspergillus clavatus, A. glaucus, A. nidulans, A. oryzae, A. terreus, A. ustus and A. versicolor are among the other species less commonly isolated.

DISEASE PREDISPOSITION

Susceptibility to disease is greatly increased when the immune system is impaired. Immunosuppression is the major factor predisposing birds to the development of opportunistic *Aspergillus* infections. *Aspergillus* spores are widespread in the environment, and many birds may carry them in their lungs and air sacs until immunosuppression or stress triggers clinical disease (Fig 29.1).

Stress alone (a strong immune suppressor) or other factors related to confinement, poor husbandry practice, malnutrition, pre-existing disease and the prolonged use of antibiotics and steroids increase the predilection to disease. 73,95 Overpopulated, poorly ventilated and dusty aviary environments lead to pulmonary and air sac disease. Research has confirmed a causal relationship between high concentrations of Aspergillus spp. spores in the environment and aspergillosis. Damp feed or bedding in warm, humid environments and poor ventilation allow for a high concentration of Aspergillus spores to develop.87 Corncob and walnut shell litters can grow Aspergillus spp. in aviary environments. Inhalation of large numbers of spores may occur. Birds exposed to the organism in quantities sufficient to establish a primary infection have developed acute disease. There is often a correlation between poor husbandry and a high concentration of spores. Eucalyptus leaves, which have been promoted as a "natural" insect repellent, are often heavily contaminated with this fungus. Acute, severe, untreatable aspergillosis has been associated with their use. 43 Aspergillosis is a common sequela to other respiratory tract disease. A predominantly seed diet, with subsequent malnutrition including vitamin A deficiency, can lead to squamous metaplasia of the oral and respiratory epithelium and the establishment of fungal growth.73 The incidence of fungal disorders is negligible in an avian practice where the majority of parrots are fed a

formulated diet (G.J. Harrison, personal communication, 2003) (see Chapter 4, Nutritional Considerations).

Aspergillosis is the most commonly occurring respiratory disease in captive wild birds.95 Of the psittacine species, the African grey parrot (Psittacus erithacus) and pionus parrots (Pionus spp.) are reported to have an increased susceptibility to the development of disease.9 Localized infection of the nasal passages is observed in Amazon parrots, possibly due to the higher incidence of hypovitaminosis A in this species.9 Raptorial species at particularly high risk of developing aspergillosis include goshawks (Accipiter gentilis), rough-legged hawks (Buteo lagopus), immature red-tailed hawks (Buteo jamaicensis), golden eagles (Aquila chrysaetos) and snowy owls (Nyctea scandiaca). 39,92,95 Gyrfalcons (Falco rusticolus) are believed to be especially susceptible to Aspergillus infection^{39,42,92,95}. Among waterfowl, a higher incidence of aspergillosis is seen in swans (Cygnus spp.). Captive penguins (Sphenisciformes) also are extremely susceptible to developing the disease. In these species, the increased incidence of aspergillosis may reflect environmental and husbandry deficiencies occurring in captivity and/or increased species susceptibility.

ASPERGILLUS PATHOGENESIS

Aspergillus spp. are widespread in nature. Birds are exposed to fungal spores on a regular basis, and many carry them in their lungs and air sacs without ill effect. The nature of disease that occurs is thought to depend on the resistance of the avian host and the number and distribution of fungal spores.⁸ Healthy birds exposed to high concentrations of spores can be resistant to infection, whereas immunocompromised patients can become severely affected by minimal exposure.^{48,122}

Aspergillosis is usually contracted as the result of a susceptible host inhaling fungal spores. Oral ingestion of spores from moldy feeds may also occur. The fungus is, however, capable of penetrating broken skin and eggshells and can infect developing embryos during the incubation process.

In birds, aspergillosis is predominantly a disease of the lower respiratory tract that usually occurs secondarily to other disease or immunosuppressive processes. Acute and chronic forms of the disease can occur. Infections may be localized or diffuse, depending upon the distribution and growth of fungal organisms. Initial lesions occur mainly in the lungs and air sacs, although the trachea, syrinx and bronchi also may be affected. Infections may spread from the respiratory tract to pneumatized bone or enter the peritoneal cavity by direct extension through the air sac walls. The organism may reach various other tissues by vascular invasion and embolism. The fungus

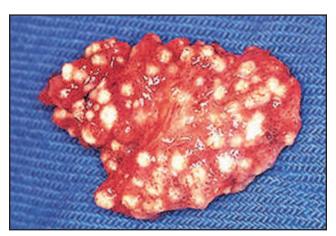

Fig 29.2 | Miliary lung nodules due to inhalation of Aspergillus spp. spores.

can infect any organ. Aerogenous and hematogenous dissemination result in diffuse, systemic disease.⁴⁹

In the acute disease, whitish mucoid exudates of fungal growth are present in the respiratory tract. Marked congestion of the lungs and thickening of the air sac membranes occur. Miliary foci of inflammation develop around sites of fungal growth and result in the formation of micronodules (Fig 29.2). 66,120 These predominate in the caudal thoracic and abdominal air sacs and peripheral lung fields. In the chronic form of the disease, multiple nodules may coalesce into plaques and larger granulomatous lesions. Sporulating fungal colonies may develop in the center of these lesions, with extensive adhesions forming between the air sac membranes, lungs and abdominal viscera.

Some *Aspergillus* spp. produce mycotoxins that are immunosuppressive and may be involved in the pathogenesis of the disease. Some mycotoxins also possess carcinogenic activity. Of these, aflatoxin is well known and may induce hepatocellular carcinoma or hepatic fibrosis with subsequent cirrhosis when ingested. Aflatoxins are most commonly associated with *Aspergillus flavus* and may contaminate feeds such as peanuts.⁷⁷

DISEASE

Clinical signs associated with aspergillosis are variable and depend upon such factors as the pathogenesis of initial infection, location of lesions, organ systems involved and host immune defenses. The disease may be either localized or diffuse and often causes a progressive, debilitating illness with high mortality. Aspergillosis predominantly affects the upper and lower respiratory tract, however, any organ system may be involved. Both acute and chronic forms of infection are commonly recognized in birds.

Acute Disease

Acute aspergillosis is a fatal respiratory disease characterized by variable morbidity and high mortality. It is usually seen in young and newly captive birds and occurs when an immunocompromised host inhales an overwhelming number of spores. Onset of clinical disease is rapid and followed by death within several days. Affected birds may show dyspnea, cyanosis, lethargy, anorexia, polyuria, polydipsia and sudden death. A white mucoid exudate and marked congestion of the lungs and air sacs occur. Numerous, diffusely distributed foci of pneumonic nodules also may be variably present.

Acute aspergillosis has been reported to occur in psittacine chicks. Host are septicemic and acutely depressed when illness is observed. In addition to tachypnea, dyspnea and vomiting, abdominal enlargement due to ascites formation frequently develops. The disease is rapidly fatal with few chicks surviving long enough to develop pulmonary granulomas.

Mycotic Tracheitis

Mycotic tracheitis refers to a form of aspergillosis localized in the trachea, syrinx and major bronchi. The pathogenesis is similar to that for acute aspergillosis in an immune-compromised host with exposure to numerous fungal spores. Colonization may occur anywhere along the length of the trachea, but is most often found at the level of the syrinx and tracheal bifurcation (Fig 29.3). Granuloma formation causes a progressive course of life-threatening obstructive airway disease (Fig 29.4). A change in vocalization may be present and is highly suggestive of lesions in the syrinx. Birds also may present with a rapid onset of severe dyspnea, open-mouthed breathing, gurgling respirations or a cough. Sudden death also may occur.

Chronic Disease

Chronic aspergillosis is the more commonly observed form of the disease. It generally occurs in older birds that have been in captivity and is the result of long-term malnutrition and stress. Previous disease, prolonged antibiotic or corticosteroid therapy and other stress factors are contributory. Some form of immunosuppression is implicated in the chronic disease. This form is often seen in species like the African grey parrot, pionus parrot and Amazon parrot.

Chronic forms of the disease can be quite subtle in onset, and early clinical signs are often non-specific. A change in behavior, reduced level of activity and decreased appetite may be observed. In some instances, exercise intolerance and weight loss, even in light of a good appetite, are the only signs noticed.⁷³ Birds with

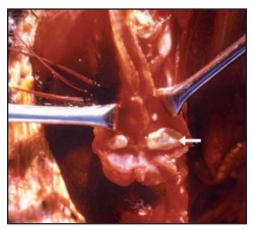

Fig 29.3 | Granuloma (arrow) of the syrinx in a blue-headed pionus parrot (Pionus menstruus). The owner noted a characteristic change and weakness in vocalizations several days prior to finding the bird deceased.

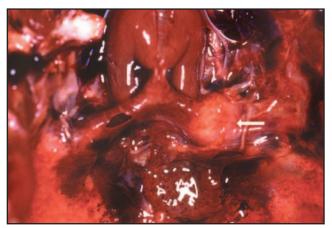

Fig 29.4 | Aspergillus granuloma (arrow) occluding the left bronchus in an African grey parrot (Psittacus erithacus).

lower respiratory tract involvement may exhibit variable respiratory compromise, depending upon the nature and extent of the lesions present.53 With the exception of the acute form and mycotic tracheitis, lower respiratory tract aspergillosis is often inapparent. Respiratory signs are usually absent until the disease is extensively developed.87 Tachypnea and dyspnea are not commonly observed until late in the disease process.59

Hepatic signs (biliverdinuria and hepatomegaly) and renal signs (polyuria, polydipsia and renomegaly) may be present. Ascites also may occur. Gastrointestinal involvement (regurgitation, diarrhea and abnormal droppings) is less frequently observed.

Aspergillus air sacculitis is the most frequently encountered form of the disease with extension to the lungs commonly occurring.87 Aspergillomas may be found throughout the entire respiratory tract but most commonly occur in the posterior thoracic and abdominal air sacs (Figs 29.5, 29.6). In advanced cases, changes occur in the respiratory rate and effort and in vocalization. Dyspnea and tachypnea in an unstressed bird, tail bobbing, open-mouthed breathing and audible respiratory sounds are indications of advanced lower respiratory tract disease. 24,59,87,112 Although auscultation is less valuable in avian patients than in mammals for evaluation of respiratory tract disease, abnormal crackles or clicking noises can indicate air sac involvement.24

The time from onset of clinical signs to death ranges from less than 1 week to over 6 weeks.73 Aspergillus hyphae are tissue- and angio-invasive and can cause respiratory hemorrhage and acute death in affected birds at any stage of the disease process (Fig 29.7).

Localized aspergillosis involving the upper respiratory

tract often presents as a chronic rhinitis and sinusitis in psittacine birds. Distension of the infraorbital sinus and periorbital soft tissue swellings may be present. Birds may exhibit a unilateral or bilateral nasal discharge that can be serous to purulent in character.87 Formation of rhinoliths and oronasal granulomas may occur and often obstruct the upper airways, causing wheezing respiratory sounds. Secondary bacterial sinus infections are common. In psittacines, obstruction of the connection between the right and left nares may occur with Aspergillus rhinitis. This obstruction may be due to the presence of caseated debris or bony deformation from chronic infection.

Central Nervous System

Encephalitic and meningoencephalitic lesions may occur with disseminated aspergillosis. Necrotizing aspergillosis with dissemination of thrombi to the brain and spinal cord is often associated with ataxia or paralysis, incoordination, tremors and torticollis.73,95 A trumpeter swan (Cygnus buccinator) with ataxia, incoordination and heart murmur had cerebral aspergillomas and Aspergillus granulomas in both ventricles of the heart.5

Ocular Mycoses

Fungal infections of the eye are rare in birds but have been reported in numerous species. 22,56 Aspergillus fumigatus was isolated on conjunctival culture from a bluefronted Amazon parrot (Amazona aestiva) with mycotic keratitis.56 It was implicated as a cause of severe blepharitis and dermatitis of the eyelids in a falcon/gyrfalcon hybrid (Falco peregrinus X Falco rusticolus) and keratitis in chickens. 1,10 Most reported occurrences result from the extension of preexisting upper respiratory infections, although ocular trauma and corticosteroid therapy

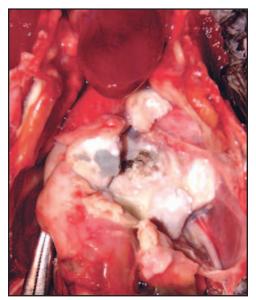

Fig 29.5 | Aspergillus fumigatus granuloma exhibiting conidiophore growth in the lung and air sacs of an African grey parrot (*Psittacus erithacus*).

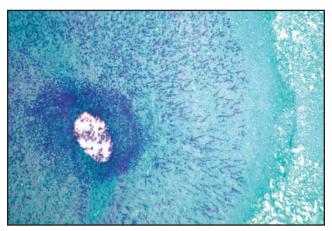

Fig 29.6 | Fungal granuloma in avian lung tissue, central area of necrosis with fungal hyphae. PAS fungal stain.

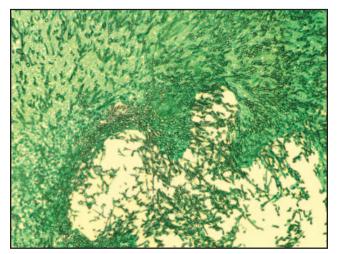

Fig 29.7 | Mycelial growth of Aspergillus fumigatus throughout an avian pulmonary granuloma. PAS fungal stain.

are other predisposing factors. 10,56,64 Affected birds may show blepharospasm, photophobia, severe periorbital swelling and conjunctival hyperemia. 22,56 Corneal epithelial erosions and stromal necrosis may result in perforation of the cornea or panophthalmitis, resulting in functional loss of the eye. 56 Characteristic signs with recent stress and/or poor nutrition should make aspergillosis a strong presumptive diagnosis.

ASPERGILLUS DIAGNOSIS

Antemortem diagnosis of aspergillosis is challenging and often requires several diagnostic methods.^{15,79} A presumptive diagnosis is often based upon the clinical history, physical exam, clinical impression, complete blood count, radiography and endoscopy. History of a previous stressful event, an immunosuppressive disease or treatment and/or exposure to spore-laden environments is supportive. Clinical signs, especially dyspnea, weight loss, exercise intolerance and chronic debilitation, also suggest aspergillosis; however, a definitive diagnosis requires confirmation of the organism by cytology, culture, histopathology or DNA testing.^{8,15,59} Demonstration of the causal agent consistent with the clinical disease and observed lesion(s) is the diagnostic goal.

Hematology and Serum Chemistry

Aspergillosis generally causes a significant heterophilic leukocytosis (25,000 cells/µl to 100,000 cells/µl), which may be associated with both acute and chronic disease. ^{15,18} White blood cells are often very reactive and a left shift may be present. Heterophils often exhibit degranulation and other toxic signs. Reactive lymphocyte changes also occur and may result in a marked lymphopenia, especially in Amazon parrot species. ⁴⁴ A monocytosis is often observed in chronic forms of the disease. ¹⁹

A non-regenerative anemia due to the chronic inflammation of the disease is often present. Lack of an appropriate bone marrow response may be evidenced by the absence of polychromasia, reticulocytosis, macrocytosis and/or anisocytosis.⁶⁰ Psittacosis and mycobacteriosis can induce similar hemograms.

Serum biochemistry analysis may show an increase in aspartate aminotransferase (AST), lactate dehydrogenase (LDH) and serum bile acids if liver involvement is present. Hypoalbuminemia and hypergammaglobulinemia also are characteristic of the disease.⁸⁷

Plasma protein electrophoresis may help support the diagnosis of aspergillosis in psittacine birds but is not specific for this disease. Observed changes in the plasma protein electrophoretograms are indicative only of a non-specific inflammatory response.

In one study, most (6/7) birds exhibited moderate to marked decrease in the plasma albumin to globulin ratio. ⁵⁸ Some (3/7) birds showed a moderate to marked increase in β -globulin concentrations. Affected birds may, however, demonstrate normal values for these indices.

Serology

Aspergillus antibody titers have only a moderate predictive value in disease diagnosis. The indirect ELISA assay (The Raptor Center, University of Minnesota) measures Aspergillus antibody levels and has shown useful correlation with clinical infections in raptor species, although false-negative results can occur.95 The test requires species-specific antibody conjugates and is most useful in these species. In a report of falconiform birds with confirmed aspergillosis, 43% (10/23) of the birds had moderate to marked antibody titers, whereas 22% (5/23) had negative titers.93 In contrast, all 112 owls described in the same report had negative antibody titers despite confirmed aspergillosis in some of these birds. In a study of captive penguins (Spheniscus humboldti, Spheniscus magellanicus, Pygoscelis adeliae) with confirmed aspergillosis, many birds had markedly increased titers and only 20% had negative antibody titers.⁹⁶

A negative antibody titer in an infected bird may be explained either by a lack of reactivity between the test conjugate and patient immunoglobulins or by a lack of patient humoral response (immunosuppression). Lack of humoral response also has been attributed to sequestration of the infection site.26 In raptors, indirect ELISA values in the mid to high range help confirm the diagnosis when aspergillosis diagnosis correlates with the clinical signs shown by the patient.93 A positive result means active infection, long-term exposure or previous infection antibody.95 The test should be utilized with hematology, endoscopy, radiology, and tracheal or air sac culture in potential aspergillosis cases. With treatment, the antibody titer generally rises, and with successful treatment then falls to undetectable levels. Failure of the titer to rise or subsequently drop with treatment is a poor prognostic sign.15

Aspergillus antibody testing is probably less useful in psittacine species. In a report documenting the sensitivity of serologic testing in detecting aspergillosis in psittacine birds, Aspergillus antibody and antigen ELISA titers in infected birds were weakly positive.⁵⁸ The incidence of weakly positive antigen titers in clinically normal birds is reported to be high, making these results difficult to interpret clinically.^{26,58} Currently, there is no hematologic test that can reliably detect aspergillosis in psittacine birds.⁵⁸

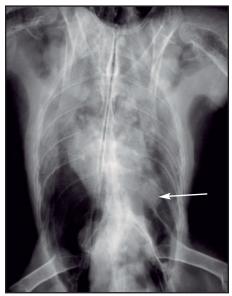

Fig 29.8 | Radiograph of an Aspergillus granuloma (arrow) in the air sac of a blue and gold macaw (Ara ararauna).

Radiology

Radiographic evaluation can demonstrate the distribution and severity of mycotic lesions in the lungs and air sacs but is usually of limited diagnostic value until late in the disease process. Although mycotic air sacculitis with granuloma formation is well documented in a variety of avian species, lesions are usually advanced before becoming radiographically apparent. 24,87,112 A bronchopneumonia with marked parabronchial patterns is one of the more common radiologic findings.73 The fibrinous air sacculitis associated with aspergillosis allows for radiographic visualization of the air sac walls.87 Asymmetry, hyperinflation or consolidation of the air sacs may be evident. A nodular air sacculitis with focal air sac densities is often seen and occurs primarily in the abdominal and, less often, thoracic air sacs. Single or multiple soft tissue densities in the air sacs or lungs are most often granulomas but should be considered non-specific (Fig 29.8).73 Although intraluminal granulomas of the syrinx, trachea and main stem bronchi are fairly common, they are seldom visualized radiographically. The syrinx is often obscured by soft tissue and bone.87 Fungal air sacculitis usually causes plaque-like and nodular granulomatous lesions in the air sacs. Even after the successful resolution of clinical Aspergillus infection, lungs and air sacs may remain thickened and irregular and appear abnormal both radiographically and via endoscopic examination.

Computed tomography (CT) scans provide a detailed image of all parts of the respiratory tract and are useful for demonstrating small lesions that are not visible on radiographs and for visualizing lesions in the infraorbital sinus, retrobulbar area, trachea and main stem bronchi.⁸⁷

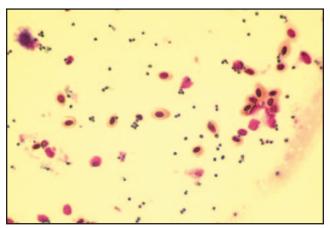

Fig 29.9 | Aspergillus spores and avian red blood cells from a clinical sample obtained during diagnostic endoscopy.

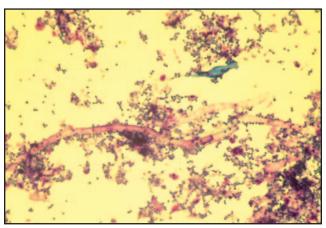

Fig 29.10 | Hyphal elements and spores of Aspergillus fumigatus in Gram's-stained clinical specimen collected at endoscopy.

A concurrent hepatomegaly and renomegaly may be visualized on radiography or detected by abdominal palpation.⁵⁹

Endoscopy

Air sac consolidation and granulomas can obscure radiographic detail in the coelomic cavity. Lesions are often best observed by endoscopy, which is an efficient way to detect and sample fungal plaques in the trachea, syrinx or lower respiratory tract.^{94,109}

The trachea (depending on species and the size of scope being used) can be visualized down to the level of the syrinx with both rigid and flexible endoscopes. Depending on the extent of the disease and chronicity of the condition, air sacs that are normally thin and transparent may be thickened, cloudy or covered with exudate. Early in the disease process, prominent vascularity of the air sacs may be the only observable abnormality.95 Fungal air sacculitis usually causes plaque-like, coalescing and nodular granulomatous lesions in the air sacs. Plaques vary from white to yellow in color to green to black on the surface, owing to the development of conidia and fungal spores.⁹⁷ The observation of typical lesions by endoscopy with biopsy sample collection for cytology, histopathology or fungal culture can provide a confirmed diagnosis of aspergillosis. Endoscopy is useful in evaluating the extent of infection and monitoring progress during treatment94 (see Chapter 1, Clinical Practice and Chapter 24, Diagnostic Value of Endoscopy and Biopsy).

Cytological Evaluation

Cytologic evaluation of clinical samples can aid the diagnosis of aspergillosis. Choanal swabs, infraorbital sinus aspirates, tracheal and air sac swabs and washings may reveal *Aspergillus* hyphae and spores (Fig 29.9).8 Squash preparations of wet mount clinical specimens are prepared and stained with lactophenol cotton blue or meth-

ylene blue stain.⁹⁵ Microscopic evaluation often reveals long, dichotomously branched (\sim 45°), septate hyphae, 2.5 to 4.5 μ m in diameter. Fruiting bodies with spores also may be identified (Fig 29.10).

Confirming the Diagnosis

Histopathology and fungal culture can be used to demonstrate the organism in clinical samples and are important in providing a confirmed diagnosis of the disease. DNA probe testing of clinical specimens also can validate the diagnosis. Tracheal swabs or air sac swabs and granuloma biopsy specimens obtained at endoscopy can be tested specifically for *A. fumigatus*. Genusspecific probes can be used to test for *Aspergillus* spp. in general. Research on the use of DNA probe testing of whole blood samples suggests that this may be helpful in providing a confirmed diagnosis of the disease.

TREATMENT

Amphotericin B

Amphotericin B^b is an amphoteric polyene macrolide anti-fungal agent.⁷² Its mechanism of action is to bind ergosterol, the principal sterol present in the cell membrane of sensitive fungi.⁶⁵ It has a wide spectrum of activity, being fungicidal to both *Aspergillus* spp. and *Candida* spp., and to other fungi including *Blastomyces*, *Coccidioides*, *Histoplasma*, *Sporotbrix* and *Mucor* spp.

Amphotericin B^b has been used to treat both systemic and topical fungal infections in birds.³⁸ It can be administered intratracheally, intravenously, in sinus flushes and through nebulization. Parenteral use quickly establishes fungicidal concentrations, making it a frequent choice for initial therapy. The drug is eliminated by the kidneys and is used for only short duration due to the risk of induced nephrotoxicity. A dose of 1.5 mg/kg IV is administered q8h for a period of 3 to 5 days and in combination with

itraconazole^c, fluconazole^d or terbinafine^f orally.³⁸ Combined nebulization therapy with clotrimazole^c or terbinafine also is suggested (see Chapter 9, Therapeutic Agents).

Sinus and tracheal aspergillosis are more difficult to treat. Intratracheal use of amphotericin B^b at 1 mg/kg q8-12 h has been described as supplemental treatment for these infections. Topically, the drug can be very tissue irritating and must be diluted in water (saline inactivates amphotericin B^b) to reduce the risk of iatrogenic sinusitis or tracheitis. ⁵⁹ Nebulization with amphotericin B^b has been reported to cause severe bronchoconstriction in horses. ¹³ Amphotericin B^b has been used in nebulization and sinus flushes for 20 years in avian species with good success and no clinical complications.

Itraconazole

Itraconazole^c is one of the most widely used antifungal agents in birds and is especially effective in combination with nebulized clotrimazole^c and/or intravenous amphotericin B^b.^{40,81,95} It has greater efficacy than ketoconazole^c or fluconazole^d against *Aspergillus* spp. and has less potential toxicity than amphotericin B^b.^{47,95,115} It has been used effectively to treat aspergillosis in raptors, psittacine birds and waterfowl, and is a recommended treatment of choice in these species.^{38,40,81,95}

Itraconazole^c is eliminated by hepatic metabolism and is generally well tolerated during long-term use.83 The effective drug dose and potential for adverse effects is variable among avian species. In most psittacine species, effective serum concentrations are attained when therapy is initiated at 5 to 10 mg/kg PO twice daily for 5 days, then once daily for the duration of treatment.82,87 Temporary anorexia and lethargy were the only side effects observed in an orange-winged Amazon parrot (Amazona amazonica) treated with 5 mg/kg itraconazole^c for 1 year.⁸³ African grey parrots are reportedly more sensitive to itraconazole^c and may exhibit adverse drug effects at normal dosage levels. One report suggests that the drug may have contributed to several deaths in this species.83 A dose of 2.5 to 5.0 mg/kg PO q24h is recommended for use in African grey parrots.87

Itraconazole^c is safe in raptors when dosed at 10 mg/kg per day PO for 3 to 6 months duration.⁶¹ Hawks treated at this level reached steady state plasma levels within 2 weeks, with effective organ tissue levels adequate to treat most fungal infections.⁶¹ Poor distribution in the respiratory tissues after oral dosing in pigeons has been reported, which might limit applicability in this species.⁷⁰ A dose of 6 mg/kg q12h in pigeons achieves effective plasma concentrations; however, a comparatively higher dose of 26 mg/kg PO q12h is needed to attain effective

respiratory tissue levels.70

Itraconazole^c is marketed as capsules containing coated lactose granules, which are soluble only at low pH. Dissolution of these granules in acid solutions results in improved bioavailability and higher blood itraconazole^c levels following oral administration in avian patients. 61,83 Absorption also is enhanced when the drug is administered with a fatty meal.82 It is recommended that itraconazole^c beads from a 100-mg capsule be divided into five equal parts of 20 mg each. Each 20-mg aliquot is dissolved in 0.4 ml of 0.1 N HCl. The resulting solution is diluted to a final concentration of 5 mg/ml by the addition of orange juice.61 For avian dosing, the drug is administered by gavage with food. Itraconazole^c also is available in a 10 mg/ml liquid^c for oral administration that avoids any concern with sufficient dissolution or suspension.

Other Agents

Fluconazole^d is effective against aspergillosis although generally less so than itraconazole^c. It is rapidly absorbed with high bioavailability after oral administration. The drug is widely distributed to the extracellular space, making it useful for treating mycoses of the eye and central nervous system.⁷¹ *Aspergillus* keratomycosis in a blue-fronted Amazon parrot was treated with oral and topical fluconazole^d.⁵⁶ A dose of 5 to 15 mg/kg PO q12h is recommended in most psittacine species.²¹

Clotrimazole^e and enilconazole^k are relatively insoluble and useful against aspergillosis only at sites that can be treated topically with the drug or reached by inhalation or nebulization. Miconazole^k is effective for treating fungal keratoconjunctivitis when used in an ophthalmic form with frequent medication intervals (q3-4h).^{4,14,41,56}

Terbinafine hydrochloride^f is a synthetic allylamine antifungal agent that is fungicidal against a wide variety of dermatophytes, molds and fungi. The drug's efficacy is similar to or more effective than amphotericin Bb and itraconazole^c against Aspergillus spp., and has been used to treat aspergillosis effectively in psittacine species.28 In addition to its fungicidal property, terbinafine¹ has good ability to penetrate mycotic granulomas. It is readily absorbed after oral administration and has a low potential for adverse side effects. No signs of toxicosis were observed during prolonged drug administration in psittacine birds.²⁸ The drug has proven very useful as an alternative treatment for avian aspergillosis, especially in cases where more conventional therapies have been ineffective. The combination therapy of terbinafine at 10 to 15 mg/kg PO q12-24h with iatraconazole^c is a safe and very effective treatment for systemic avian fungal disease.

Nebulization Therapy

Aerosolization therapy is used to augment systemic treatment by delivering drugs directly to the respiratory tract. Target tissues receive high concentrations of the drug while minimizing systemic exposure.¹³ In addition, hepatic first-pass metabolism following oral administration is circumvented.¹³ Clotrimazole^e supplied as a 1% solution can be used for nebulization therapy at 30 minutes q24h.⁶³ However, a 15% aqueous suspension can be compounded, which appears to be more effective than the commercial form (P. Redig, personal communication, 2003). Terbinafine hydrochloride^f nebulized as a 1 mg/ml aqueous solution (20 minutes q8h) was effective in resolving a non-responsive respiratory aspergillosis in a 6-year-old Congo African grey parrot (*Psittacus erithacus*).²⁸

A commercially available disinfectant⁸ is useful for treatment of birds within their quarters or en masse when nebulized at a 1:250 aqueous dilution. Nebulization therapy q12h for 3 to 12 weeks has been successful in the treatment of aspergillosis in a 12-week-old Congo African grey parrot and effective in combination with itraconazole^c for raptorial species.^{7,107} It also can be used to fog aviary rooms and pigeon lofts to reduce the level of fungal contamination in these premises¹⁰⁷.

Surgical Treatment

Treatment of respiratory aspergillosis is clinically challenging. Granulomatous lesions may occlude vital respiratory pathways or prove resistant to therapy because of poor drug penetration into the encapsulated lesions. ^{24,87,112} If nebulization and systemic administration of antifungal agents is not effective, surgical debulking of granulomas may be necessary. ⁸⁷ For infections of the sinus cavities, trephination of the frontal sinuses permits direct access to granulomas for debridement and topical application of medications in an otherwise inaccessible site. ⁸⁷

Rhinitis or sinusitis of *Aspergillus* origin may require enzymatic therapy to dissolve the caseated debris and allow flushing of the affected area with the appropriate antifungal agent. Both hyaluronidase and trypsin-based flushes have been used for this purpose.

Tracheal and syringeal granulomas may precipitate lifethreatening respiratory tract obstructions. Granulomas often form just proximal to or at the bifurcation of the trachea. Birds can effectively ventilate through cannulae placed in the clavicular, caudal thoracic or abdominal air sacs. 33,51,98,101 These can provide an alternative airway in emergency cases of tracheal obstruction and can be used for both short- and long-term duration. They can be left in place for periods of up to 1 week, but should be removed when possible to prevent iatrogenically induced air sacculitis. 89,101

Cannulae also may be used to induce and maintain anesthesia during tracheal, syringeal or oral surgery. For suspected tracheal granulomas, an open-end tom cat catheter can be used to obtain clinical samples and for suction therapy to cannulate the tracheal lumen. Tracheotomy, through a ventral midline incision centered over the thoracic inlet, may be used to access granulomas in the tracheal lumen. ^{30,89} If the granuloma is at the level of the syrinx, blunt dissection through the interclavicular air sac or an alternative left lateral approach may provide needed access. ⁸⁹ A clavicular osteotomy may be necessary to improve surgical access to the syrinx in some birds. ⁸⁹

Fungal granulomas of the lower respiratory tract are often resistant to medical therapy. ^{24,87,112} Surgical resection of these masses has been recommended; however, little has been published about techniques and their respective success. ^{24,89,109} Attempts at surgical removal are often incomplete due to the location of granulomas within the respiratory tract and the need to minimize trauma to adjacent structures. ⁵³ Endoscopy allows access to most of the lower avian respiratory tract with minimal trauma and is an alternate approach for removing these lesions. ¹⁰⁹ A detailed knowledge of the avian air sac system and competence with the rigid endoscope is a prerequisite before attempting this procedure ⁵³ (see chapter 24, Diagnostic Value of Endoscopy and Biopsy).

A recent report describes endoscopic debridement and laser ablation as a viable alternative to conventional surgery in the management of lung and air sac granulomas.⁵³ A gallium-aluminum-arsenide diode laser, employing flexible fibers passed through the operating channel of the rigid endoscope, was used to ablate remaining granulomatous tissues in the air sacs after endosurgical debulking.⁵³ A small volume of amphotericin B^b was used to sterilize the remaining lesion. Greater clinical success was achieved by endosurgical debridement and laser ablation, compared with conventional surgical exploration and removal of granulomas or medical therapy alone.⁵³

Summary

In treating aspergillosis, proper supportive care including heated environment, fluids and nutritional support are essential. Because affected birds are severely compromised, the risk of secondary bacterial infections is significant. Antibiotic therapy is indicated. Prolonged antifungal therapy for periods up to 4 to 6 months is often necessary for treatment success.

Patients should be closely monitored for clinical improvement and observed for any signs of toxicosis during this period. Treatments are usually continued for 1 month after the complete blood count has returned to normal.⁸⁷ Aspergillosis is a preventable disease. Proper

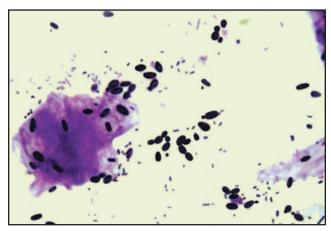

Fig 29.11 | Candida albicans in an avian fecal Gram's stain. Yeast in this form proliferates in the lumen of the digestive tract and is responsive to topically acting antifungal agents (nystatin^h).

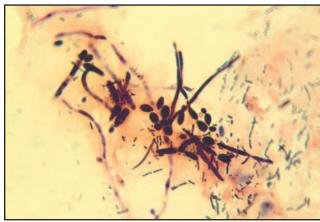

Fig 29.12 | Candida albicans exhibiting mycelial growth in a fecal Gram's stain from a cockatiel (Nymphicus hollandicus). Yeast in this form is tissue invasive and requires systemic antifungal therapy for proper treatment.

diet and husbandry practices to reduce stress and provide good hygiene will reduce factors that predispose to the development of this disease.

Candidiasis

Candidiasis in birds, also known as thrush, moniliasis or sour crop, refers to infections by yeasts of the genus *Candida. C. albicans* is the most commonly implicated species, although *C. parapsilosis*, *C. krusei*, and *C. tropicalis* also may cause disease. 103

C. albicans is an opportunistic yeast and not regarded as a primary pathogen. Small numbers of the non-budding organism are commonly found in the digestive tract of normal birds and considered normal flora in healthy pigeons. ¹⁰² Host defense mechanisms and bacterial flora keep numbers of the organism controlled. *Candida* spp. can proliferate and cause disease when digestive tract flora are severely suppressed. In most cases, the infection is endogenous in origin, occurring secondarily to stress, immunosuppression, inadequate nutrition, poor sanitation, debilitation or in birds that have been extensively treated with antibiotics.

This disease is most often seen in psittacine neonates and cockatiels. Yeasts gain entry into the host by the oral route. 102 The organisms can be transmitted from the parent bird to chicks during regurgitative feeding. The infection also may be spread throughout the nursery population by the use of contaminated fomites and feeding utensils.

Candidiasis affects the mucocutaneous areas of the body and gastrointestinal mucosa, particularly of the oropharynx, crop and esophagus. Affected birds are depressed and may exhibit delayed crop emptying, regurgitation, crop stasis, inappetence and poor digestion of food. Droppings are often abnormal, appearing brownish in color and watery. Affected chicks do not grow or gain weight well and appear stunted.

Lesions vary in severity. They consist of thickening of the digestive tract mucosa with increased mucous and pseudomembranous patches. The choanae may become abscessed with formation of a diphtheritic membrane in the oropharynx as mycelial growth develops. Whitish plaques may be evident under the tongue, in the mouth and most frequently in the crop. In advanced cases, stomatitis and palpable thickening of the ingluvies are present. Endoscopic examination of affected membranes of the oropharynx, crop, esophagus, proventriculus and ventriculus may reveal white-grey to grey-green, thickened and diphtheritic membranes. A characteristic "Turkish towel" thickening of the crop lining is evident in advanced cases.

Diagnosis is made by identifying the organism on wet or Gram's-stained smears from lesions in the oral cavity, crop or cloaca (Fig 29.11). Crop washings and fecal samples also may be used. *Candida albicans* grows as a budding yeast cell, oval in shape, 3.5 to 6.0 x 6.0 to 10.0 μ m in size. High numbers of budding yeast confirm the diagnosis. The presence of elongated pseudohyphae suggests more severe infection with deeper tissue involvement (Fig 29.12). The organism can be cultured on mycological agar with cycloheximide and chloramphenicol at 37° C for 24 to 48 hours. Growth appears as shiny and convex round colonies measuring 3 to 5 mm in diameter, pearl white to light cream in color.

Differential diagnoses for inflammation of the upper gastrointestinal tract include bacterial stomatitis, trichomoniasis, capillariasis and nutritional disorders (see Chapter 4, Nutritional Considerations).

TREATMENT

Correction of the diet and husbandry are necessary for successful treatment of candidiasis. Nystatin^h is the first drug of choice for yeast infections confined to the alimentary tract. It is not absorbed from the digestive tract and is effective for oral or topical use only. Nystatin^h is fungistatic in action and must come in contact with the organism to be effective. Oral lesions may not respond if the drug is administered by gavage tube beyond this site of infection. The drug also can be applied directly to lesions of the mucous membranes in the oropharynx. The recommended dose of 290,000 units/kg PO q8-12h is safe and effective for use in psittacine neonates.²¹ For flock treatment, nystatin^h can be added to the drinking water at 100,000 IU/L.¹⁰²

Severe yeast infections may be refractory to nystatin^h therapy. If the organism is resistant to nystatin^h or is in the hyphal stage, having penetrated the wall of the digestive tract, systemic antifungals are indicated. Fluconazole^d or ketoconazoleⁱ are the systemic drugs of choice. Fluconazole^d is one of the most effective antifungal agents for the treatment of tissue-based yeast infections. A dose of 5 to 15 mg/kg PO q12h is recommended for most avian species.²¹ It also is effective against alimentary tract yeast when added to the drinking water at 50 mg/L.¹⁰² Ketoconazoleⁱ also can be used to treat systemic yeast infections at 10 to 30 mg/kg PO q12h. It can be added to the drinking water at 200 mg/L for flock treatment of pigeons.¹⁰²

Itraconazole^c has been used in the successful treatment of candidal tracheitis in a blue and gold macaw (*Ara ararauna*) and candidal infection of the uropygial gland in a king penguin (*Aptenodytes patagonicus*).⁵⁵ Some *Candida* spp. are, however, extremely resistant to itraconazole^c.¹¹⁴ The drug is unlikely to achieve therapeutic concentrations at 5 mg/kg and should be used at the higher dose of 10 mg/kg PO q24h.

Oral chlorhexidine at 10 to 20 ml per gallon drinking water for 3 weeks can be used for flock control of *Candida* infections but generally will not eliminate them. Mild cases of candidiasis may respond to acidification (see apple cider vinegar in Chapter 9, Therapeutic Agents).

Macrorhabdosis

Clinical disease caused by the organism historically known as *Megabacterium* has been referred to as megabacteriosis, *Megabacterium*-associated disease and proventricular disease in birds. ^{6,36} More recent studies have confirmed that the organism is a fungus and repre-

sents a new genus of ascomycetous yeast called *Macrorhabdus ornithogaster*.^{91,110} The clinical condition in birds is more properly referred to as macrorhabdosis. The reader is referred to Chapter 30, Implications of *Macrorhabdus* in Clinical Disorders in this text for detailed discussion on this topic.

Mycotic Dermatitis

Fungal dermatitis is rarely reported in birds, even though fungi such as *Trichophyton* and *Aspergillus* spp. have been recovered from the feathers, skin and eyes of healthy birds. 32,122 Infections of the integument caused by Candida albicans, Rhodotorula, Microsporum gallinae, Aspergillus, Rhizopus, Malassezia and Mucor species have been described. 17,25,85,118 Skin and feather lesions associated with Aspergillus have been recognized in pigeons and psittacine birds.111 Aspergillus and Alternaria spp. also have been associated with epidermal cysts in the domestic chicken. 108 Other reports of fungal dermatitis include Trichophyton in canaries (Serinus canarius), Microsporum gypseum in budgerigars (Melopsittacus undulatus), Microsporum gallinae and Cladosporium berbarum in chickens (Gallus gallus) and Candida species in gallinaceous birds. 66,105,111

Favus, commonly referred to as "avian ringworm," describes a mycotic dermatitis found primarily in gallinaceous birds. It consists of white, crusting lesions of the face, comb and wattles that can extend to the feathered portion of the head. *Microsporum gallinae* is the agent most often involved, although *M. gypseum* and *Trichophyton simii* also have been isolated.

Correction of diet and husbandry issues combined with topical and oral systemic miconazole¹ therapy is usually efficacious in treating mycotic dermatitis in affected birds.

Cryptococcosis

Cryptococcosis is most commonly caused by infection with *Cryptococcus neoformans* var. *neoformans*, an encapsulated saprophytic fungus with worldwide distribution. *Cryptococcus neoformans* var. *gatti* is more geographically restricted because of an ecological association with the river red gum (*Eucalyptus camaldulensis*) and other eucalyptus trees.³⁴ The organism is commonly found in soils contaminated with bird droppings.⁶⁸

While cryptococcosis is a rare disease of birds, disseminated infection has been reported in the green-winged macaw (*Ara chloroptera*), Moluccan cockatoo (*Cacatua*

moluccensis), thick-billed parrot (Rhynchopsitta pachyrbyncha) and North Island brown kiwi (Apteryx australis mantelli). 23,27,35,54,100 Infections may involve the respiratory tract, digestive tract and central nervous system, producing necrotic granulomatous lesions and a characteristic thick, pale, gelatinous exudate. The lower temperature of the upper respiratory tract makes it more susceptible than other areas of the body to initial colonization with Cryptococcus.23 Upper respiratory tract involvement can produce facial granulomas that distort the rhamphotheca. 20,27,31 A chronic rhinosinusitis resembling a neoplasm of the rhamphotheca was described in a Major Mitchell's cockatoo (Cacatua leadbeateri) and was due to C. neoformans var. gatti. 90 An encephalitis or meningitis also may occur, causing blindness or paralysis in affected birds. 23,35

Diagnosis of cryptococcosis should be based on cytology and histopathology in combination with culture rather than culture of nasochoanal swabs or washes alone.90 Cryptococcus neoformans var. neoformans and var. gatti may be carried asymptomatically in the upper respiratory tract. Wright's-stained smears of gelatinous material often reveal aggregates of encapsulated yeast organisms measuring 6 to 10 μ m within 8- to 12- μ m non-staining capsules.90

Veterinarians must use extreme caution when handling clinical materials that may contain Cryptococcus spores. Most human infections occur through contact with contaminated exudates, fecal material and non-clinical infected or diseased birds.74,78 While human infection with C. neoformans var. neoformans is well recognized in immunosuppressed patients, infection with C. neoformans var. gatti is commonly associated with otherwise healthy and immunocompetent individuals. 68,106

Antifungal agents such as amphotericin Bb, fluconazoled or itraconazole^c have been suggested as treatment for cryptococcosis.23 Fluconazoled administered orally at a dosage of 8 mg/kg q24h for 2 months was successful in resolving bilateral nasal cryptococcosis in an African grey parrot, but the lesions recurred 3 years later.31

Although cryptococcosis is a rare disease of birds, the zoonotic potential associated with this infection is significant. Veterinarians must be aware of this disease when diagnosing and treating upper respiratory disease in birds and must remember to discuss the zoonotic potential of this infection with their clients.

Histoplasmosis

Histoplasmosis is an infectious but not contagious mycotic disease that has been reported in poultry and

zoo specimens. The soil-borne organism Histoplasma capsulatum has worldwide distribution and is endemic in the eastern and central USA. It is commonly associated with fecal material from pigeons and gallinaceous birds, and has the potential to grow within dirt substrates of enclosed aviaries.8 Histoplasma infections in birds produce disease signs similar to those seen with Cryptococcus spp. infections. An initial pneumonia can progress to disseminated disease with the formation of necrotic granulomas. Histoplasmosis was identified as the cause of an osteomyelitis and mineralized soft tissue granuloma of the shoulder and antebrachium in a Moluccan cockatoo. 119 The infection should be considered part of the differential diagnosis of granulomatous respiratory disease in avian patients. Diagnosis is based on culture of the organism and histopathologic examination of tissue samples.

Mucormycosis

The order Mucorales includes a number of saprophytic fungi that have been implicated as possible avian pathogens. They have been implicated as an etiologic agent of meningoencephalitis in birds.11,86 Hyphal invasion of cerebral blood vessels and dissemination of an Absidia sp. in the cerebrum was identified as the cause of progressive neurologic defects culminating in seizures in a chattering lory (Lorius garrulus).80 Other clinical syndromes described include air sacculitis in a pigeon (Columba sp.), pneumonia in a rock hopper penguin (Eudyptes crestatus) and a group of rock ptarmigan (Lagopus mutus), and an osteolytic mass involving the ribs and air sacs of a penguin (Sphenisciformes). 12,50,67,84 The feeding of damp, germinated seed has been implicated in disseminated mucormycosis causing alimentary granulomas in a group of canaries (Serinus canarius) and nephritis in an African grey parrot; glossitis in an African grey parrot; myocarditis in an Australian parakeet (Psittacula sp.); and nasal infection in waterfowl. 16,29,75 Absidia corymbifera is the pathogen most often isolated, although Mucor and Rhizopus spp. also are identified.66

Antemortem diagnosis of mucormycosis is difficult because the organisms do not culture well from clinical samples.⁶⁹ Histopathology of biopsy specimens is more reliable in confirming the diagnosis.80

No effective treatment of mucormycosis in birds has been reported. Amphotericin Bb is the single most reliable agent used in humans.

Other antifungal medications including nystatin^h, 5-fluorcytosine^m, clotrimazole^e and miconazole¹ are reported to have no consistent in vivo activity against the Mucorales.⁶⁹

Dactylariosis

Dactyloriosis is a fatal encephalitis of poultry caused by *Dactylaria gallopava*. The organism grows in old sawdust and wood shavings. Infection involves the central nervous system, causing torticollis, incoordination, tremors and sternal recumbency. The respiratory system is a less commonly involved site. The signs and lesions of dactylariosis resemble those caused by aspergillosis. Culture can be used to differentiate the infection.

Implications of

Macrorhabdus

in Clinical Disorders

DAVID N. PHALEN, DVM, PhD, Dipl ABVP-Avian

Fig 30.1 | Macrorhabdus ornithogaster stained with calcofluor white M2R and viewed with ultraviolet light (380-420 nm).

History and Identification of the Organism

The information available about macrorhabdosis (aka megabacteriosis, virgamycosis, avian gastric yeast) in birds is confusing for those unfamiliar with the literature and sometimes equally as confusing for those who are. The organism was originally thought to be a yeast because of its staining characteristics.³ Subsequently, Van Herck, et al, concluded that it was a bacterium, as they were unable to demonstrate cytoplasmic organelles or a nucleus. They did, however, show nuclear-like structures in Giemsa-stained organisms but interpreted them to be "granules." 23 Scanlan and Graham reported isolating a bacterium from the stomach of budgerigars using standard microbiological techniques. The isolated bacterium, however, was smaller than the organism in vivo and was not characterized by periodic acid-Schiff (PAS) or silver stains.20 Attempts by other investigators to grow this organism with standard microbiological isolation techniques have been unsuccessful. However, Gerlach reported isolation of this organism on MRS medium, a medium used for growing fungi, but was unable to maintain it past a few passages.8 Huchzemeyer, et al, also reported isolating an organism from the proventriculus of ostriches using MRS agar. This organism had the same biochemical properties as the one isolated by Scanlan and Graham, but was smaller than those seen histologically, and its ability to stain with PAS and silver stains was not reported.9

More recent work suggested that the "megabacterium" was, in fact, a yeast. In vivo trials showed that the "megabacterium" was susceptible to amphotericin B but not to antibacterial antibiotics. 4 It also stained strongly with calcofluor white M2R (Fig 30.1) and blancophor BA, stains that bind to chitin and cellulose, products not found in bacteria. 11,16 It grows, albeit slowly, in cell culture media supplemented with dextrose, fetal calf serum and antibacterial antibiotics. A nucleus was demonstrated by electron microscopy, and in situ hybridization with a pan eukaryote rRNA probe was positive.17 Prior to conclusive determination of the genus and species to which the organism belonged, it was temporarily called avian gastric yeast. Tomaszewski, et al sequenced the ribosomal DNA of this organism and used this information to prove that it was a novel anamorphic ascomycetous yeast that belongs in its own new genus.22

Originally, it was proposed that it be named Virgamycosis avigastricus, but this name was not accepted. Subsequently, it has been named Macrorhabdus ornithogaster.22

SIGNS OF INFECTION

There are mixed opinions about whether M. ornithogaster can cause disease. Many investigators consider it to be a pathogen, while others have described it as a commensal.^{8,20} The truth probably falls in between. It is clear that under some, perhaps most, circumstances, infection with M. ornithogaster does not result in clinical signs. It is equally clear that certain individual birds will show signs that can be attributed to infection with this organism, and that the prevalence of disease may be high in some collections and perhaps in some species of birds. Whether this represents variation in the pathogenicity of different strains of M. ornithogaster or differing susceptibilities of the affected birds is not known.

Host Range

Macrorbabdus ornithogaster has a wide host range and a worldwide distribution. It was first described in canaries and has subsequently been identified in captiveraised and free-ranging finches. 3,6,13,23 The prevalence of infection in budgerigar aviaries is high, and the percentage of infected birds in aviaries where it is enzootic may range from 27 to 64%, as judged by fecal shedding. 1,4,5

Macrorhabdus ornithogaster also is commonly found in parrotlets, cockatiels and lovebirds. 5,10,14 Filippich reports that it is seen in several species of captive Australian parrots.5 Macrorhabdus ornithogaster also is reported in ostriches, chickens, turkeys, geese, ducks and two species of ibis. 8,10,12,21 It is suggested that organisms thought to be

M. ornithogaster also can infect mammals. 19 The organisms used in these experiments, however, appear to be bacteria and not M. ornithogaster, and there is no evidence at this time to suggest that it is a pathogen of mammals.

BUDGERIGARS

Filippich describes two clinical presentations in the budgerigar. In the acute presentation, apparently healthy birds suddenly go off feed, regurgitate ingesta (which may be blood stained), and die within 1 to 2 days. In the more common chronic form, affected birds typically appear to be hungry and spend considerable time at the food dish. Instead of eating, however, these birds are grinding their food but not ingesting it. Regurgitation is common, and fresh or dried saliva is often found on the tops of affected birds' heads. Undigested seeds may be present in the droppings. Diarrhea with or without melena also may be present. These birds go through a prolonged period of weight loss (going light) where they appear unthrifty and eventually die. If the affected budgerigar colony is sufficiently large, there will always be a few birds in the collection that will be showing these signs. Birds with clinical signs of infection are reported to have decreased packed cell volumes and low sodium, chloride, phosphate, glucose, cholesterol and aspartate aminotransferase values. When there was gastric ulceration, markedly low total protein concentrations were observed. Contrast radiography revealed, in some birds, a dilated proventriculus and an increased transit time. In one aviary, mature birds with a mean age of 2.7 years were most commonly affected.^{5,6} Although clinical signs are more common in middle-aged budgerigars. infection begins very early in these birds and the author has seen large numbers of organisms in the isthmus of nestling budgerigars that were only 12 days old. It is critical to note that other diseases in budgerigars also can cause similar signs; these include candidiasis of the crop or ventriculus, a bacterial ventriculitis, trichomoniasis, enteritis, heavy metal poisoning and neoplasia of the stomach.

PARROTLETS

Parrotlets appear to have an acute onset of disease where they develop regurgitation and may have melena (D. Zantop, personal communication). Infection and disease appear to be most common in the green-rumped parrotlet, especially its color mutations. 14

LOVEBIRDS

Regurgitation and weight loss were seen in two flocks of lovebirds. Organisms believed to be M. ornithogaster were found in significant concentrations in the drop-

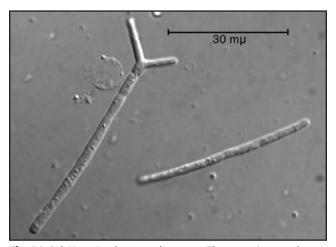

Fig 30.2 | Unstained M. ornithogaster. The organism on the right is typical. The Y-form on the left is rarely seen.

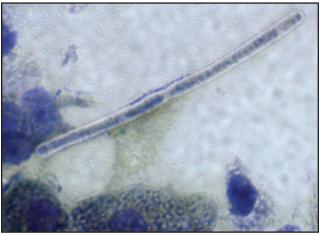

Fig 30.3 | Gram stain of *M. ornithogaster*. Only the cytoplasm stains. Often many of the organisms will stain only faintly or not at all with Gram's stain.

pings of these birds. Psittacine beak and feather disease also was found in affected birds and may have played a role in the ability of *M. ornithogaster* to cause disease in them (T. Lightfoot, personal communication, 2003). It should be noted, however, that psittacine beak and feather disease virus infection is widespread in lovebirds, so this may have been a coincidental finding.

CANARIES AND FINCHES

Signs of disease in canaries and finches are poorly defined. Most bird owners first recognize that there is a problem when a bird is found dead. Typically these birds are thin, suggesting a chronic course of disease that was unrecognized by the owner.^{3,23}

OSTRICHES

Disease in ostriches associated with *M. ornithogaster* was described in 10-day-old to 12-week-old chicks. Birds appeared normal but ceased growing and lost weight. Eventually they became weak and died. Birds had soiled vents and were anemic. Diarrhea was observed in some birds while others had dry, pelleted stools. Mortality rates varied from 40 to 80% in affected flocks.⁹

CHICKENS

Two reports describe signs that were seen in flocks of chickens naturally infected with *M. ornithogaster*. In the first report, birds were stunted and prone to eat litter and pick at each other. ¹⁰ In the second report, stunting also was seen along with increased mortality and poor laying performance. All but one of the birds in the second study had significant concurrent diseases, making it difficult to know if *M. ornithogaster* acted as a primary or secondary pathogen. ²¹ Experimental infection with *M. ornithogaster* in white leghorn chickens did not result in clinical signs of disease. However, the feed conversion

rate in infected birds was reduced compared to non-infected controls, suggesting that *M. ornithogaster* may have an important economic significance if introduced into poultry flocks.¹⁵

Detection

Macrorbabdus ornithogaster is a long, straight, narrow rod that is 3 to 4 μ m wide and 20 to 80 μ m long (Fig 30.2). It will occasionally branch, but this is rare (Fig 30.2). The longer organisms are actually chains of 2 to 4 cells, but the septations between cells are not readily observed. They are gram-positive, but many organisms will not pick up the stain or will only pick up the cytoplasm and not the thick cell wall, and therefore will stain faintly or not at all (Fig 30.3).

Similarly, *M. ornithogaster* stains poorly and variably with quick stains used for cytology.²² Also, it has been the author's impression that the organism is easily washed off slides during the staining process.

Short of a proventricular scraping or flush, there is no definitive way to detect *M. ornithogaster* infections in the live bird. Many, probably most, sick birds with macrorhabdosis will shed large numbers of organisms in their droppings. These organisms are best observed by making an unstained wet mount of a dropping and examining it under the microscope at 100x and 400x magnifications. Reducing the diameter of the stage diaphragm will make the organisms easier to see (Fig 30.4). Shedding in birds that are not showing signs of illness is highly inconsistent. Examination of five or more droppings may be necessary to find even a few organisms, and in some birds shedding will not be detected at all. The opposite also is true, in that an occasional asymptomatic bird will shed large numbers of organisms. Additionally, fecal screening

Fig 30.4 | Wet mount of a scraping from the gastric isthmus of a budgerigar with a heavy infection of *Macrorhabdus ornithogaster*. The aperture stage condenser was narrowed to increase contrast.

is complicated because feces contain debris that may be mistaken for *M. ornithogaster*.¹⁴ *Macrorhabdus ornithogaster* stained with calcofluor white M2R is readily visualized with a fluorescent microscope with excitation barrier filters (380-420 nm) (see Fig 30.1). Unfortunately, this technique is not commonly available.¹¹

Treatment Options and Interruption of the Infection Cycle

The only antimicrobial tested to date that was effective against M. ornithogaster is amphotericin B. 4,14 Treatment was effective only at a dose of 100 mg/kg by gavage twice a day for 30 days. A water-soluble preparation^a when given for 14 days was not effective. A strain of M. ornithogaster resistant to amphotericin B has been identified in Australia. 14 It is not known how widespread resistance to amphotericin B may be. Initial reports in chickens suggested that fluconazole (100 mg/kg q 12 h) showed some promise for treating this organism. Subsequent testing showed that this dose was highly toxic to budgerigars and that mortality was seen even when the dose was reduced to 10 mg/kg q 12 h. A dose of 10 mg/kg q 24 h was less toxic but was not effective.14 A single report suggested that nystatin was effective for treating M. ornithogaster in a small group of goldfinches.⁴ Nystatin, however, was not effective in budgerigars in Australia. ⁷ Iodine preparations, lufenuron, ketoconazole, terbinafine or itraconazole also were not effective against M. ornithogaster in other trials. 14 Macrorbabdus ornithogaster shedding ceased when a Lactobacillus sp. was administered by gavage in treated budgerigars.⁷ The birds were not necropsied, so it is not known if they were cured or just temporarily stopped shedding the

organism. Previous reports suggesting that M. ornithogaster is susceptible to antibacterial antibiotics were erroneous, as the organism they tested was not M. ornithogaster. ^{18,20}

Evidence suggests there are mixed benefits to treating an entire flock of birds for *M. ornithogaster*. This would require that amphotericin B be given by gavage to every bird twice a day for 30 days. Additionally, it would require that the environment be extensively cleaned and disinfected; to date it is not known which disinfectants are effective against *M. ornithogaster*. With these constraints, flock treatment is not likely to result in a flock cure. Filippich, however, suggested that treatment did result in a significant reduction of birds that were shedding the organism.⁶ Culling positive birds without treatment did not result in a reduction of shedding. However, it was suggested that culling positive birds after treatment might be of some benefit, as these birds may be infected with amphotericin-resistant strains.

An alternate approach to eliminating the infection from a flock is to incubator-hatch and hand-raise the young. Experimentally, it has been shown that if budgerigar eggs are pulled from the parents and cleaned, and the chicks are not allowed to have contact with the egg or infected birds after hatching, infection does not occur. Hand-feeding nestling day-old parrotlets and budgerigars and keeping them isolated from other birds is not an easy task, but may be one that a breeder is willing to do if this organism is a problem in a flock of valuable breeding birds.

Based on the virtual impossibility of treating large flocks for *M. ornithogaster*, the author recommends treatment of birds showing signs and selectively breeding birds that do not demonstrate signs of disease. Clinical experience suggests that some budgerigars may have a heritable resistance to infection (L. Filippich, personal communication, 1997).

It was thought that *M. ornithogaster* may cause a change in the pH of the stomach. While this seems very unlikely given that *M. ornithogaster* has little or no impact on the acid-secreting cells of the proventriculus, it has led some to speculate that administering agents that would acidify the stomach may be effective in its treatment. A controlled study testing this hypothesis failed to show efficacy of an orally administered acidifying agent.⁴

Findings at Necropsy

Gross necropsy findings are not specific. Birds are typically thin to emaciated and have little or no body fat. There may be ulceration of the ventriculus, proventricu-

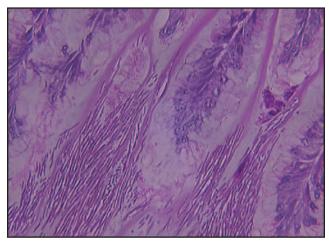

Fig 30.5 | Hematoxylin and eosin-stained section of the gastric isthmus, demonstrating the "log-jam" appearance of Macrorhabdus ornithogaster in situ.

lus or both. Most often the distal proventriculus and isthmus, the narrow zone of the stomach between the proventriculus and the ventriculus, is slightly dilated and has a thin wall. Perforation of the proventriculus is reported in some cases. Thick, opaque mucous secretions may cover the mucosa of the proventriculus and isthmus. 1,5,6 Microscopically, the organism is found on the surface of the glands of the isthmus and the transitional koilin. When present in large numbers, these organisms penetrate between the isthmus glands and invade the transitional koilin of the isthmus and the koilin of the ventriculus (Fig 30.5). When the organisms penetrate to the level of the isthmus glands, there is usually a significant accompanying disruption of the koilin. Additionally, isthmus glands appear to atrophy or undergo necrosis. Varying degrees of inflammation were observed in different studies. In the author's experience, inflammation in the budgerigar often is absent or minimal. If there is

ulceration there will be a heterophilic response. It is normal for budgerigars, particularly nestling budgerigars, to have mild to moderate lymphoplasmacytic aggregates in the lamina propria of the proventriculus and isthmus. These findings should not be interpreted as a response to *M. ornithogaster* infection. It is possible, however, that these aggregates may become larger and more extensive in some infected birds. Baker found a significant mononuclear cell infiltrate in the mucosa of budgerigars with macrorhabdosis. Birds with chronic disease also showed evidence of goblet cell hypertrophy and fibrosis of the submucosa. Glandular cysts were seen occasionally.¹

The microscopic lesions in infected chickens resemble those described by Baker in the budgerigar. The normal lymphoplasmacytic aggregates found in the lamina propria and submucosa are markedly expanded, resulting in a prominent widening of the folds of the glands of the isthmus. 12,15,21

It is important to note that infections with *M. ornithogaster* are common and are often present in birds that die from other causes. Finding *M. ornithogaster* without evidence of koilin disruption and ulceration makes it unlikely that it was the cause of death.

There are reports that *M. ornithogaster* can be found in the intestinal tract and very rarely in other organs.⁸ There are bacteria that can have a similar appearance to *M. ornithogaster*; therefore, if it is suspected that organisms outside the stomach are in fact *M. ornithogaster*, sections should be stained with a chitin-specific stain to prove that they are not bacteria.

Implications of

Toxic Substances

in Clinical Disorders

JILL A. RICHARDSON, DVM

Fig 31.1 | A lutino cockatiel with excessive yellow feather pigmentation commonly seen in nutritional disorders. Helga Gerlach first proposed that consumption of foreign bodies is mediated by nutrient imbalances. Since that time, the use of formulated diets has become much more prevalent. Practitioners have empirically noted a concomitant and precipitous decline in foreign body ingestion.

Birds are curious in nature and certain dangerous objects may be attractive to them (Fig 31.1). As most pet birds have clipped wings, remain caged or have limited activity outside their cages, toxicosis are not common. However, birds with free household access or free-ranging birds are most at risk of becoming exposed to toxicants. With any potential toxicosis, proper and prompt treatment including stabilization and decontamination is essential. Supportive care is also a critical factor in the full recovery of the bird.

Assessing the condition of the bird is the initial step in managing potential toxicosis. This assessment should be performed quickly and in a manner that will limit stress to the bird. Sedation with isoflurane or sevoflurane gas anesthesia may be required to limit stress or when dealing with fractious birds. Toxic birds are prone to both active and passive regurgitation, and care must be taken to prevent aspiration. To help decrease stress, birds should be examined and maintained in a quiet, warm environment.1 The assessment should include an evaluation of the respiratory rate and effort, capillary refill time and general attitude (see Chapter 6, Maximizing Information from the Physical Examination). The examination of a bird that is unconscious, in shock, seizuring or in cardiovascular or respiratory distress must be conducted simultaneously with stabilization measures (see Chapter 7, Emergency and Critical Care).

Stabilizing the bird is a life-saving priority.¹ Once the animal is stabilized, a comprehensive history of the bird including exposure history can be obtained. Common presentations of birds that require stabilization include dyspnea, cyanosis, severe depression, emaciation, severe diarrhea, seizures and hemorrhage.¹ Minimal handling is imperative with dyspneic birds in order to decrease

Fig 31.2 | Fluids being given subcutaneously to a toxic duck.

Fig 31.3 | Lavaging the digestive system with warmed saline via a crop tube. If lavage is contraindicated, the liquids can be used to dilute toxins and/or aspirate fluids in the crop that may contain toxins

oxygen requirements. Dyspneic birds should be placed in a cage supplemented with oxygen before and during examination.1 A diuretic may be indicated with the presence of pulmonary edema.1

Anti-convulsant therapy such as diazepam at 0.6 mg/kg IM should be given if the bird is seizuring.⁷ Intravenous, intraosseous or subcutaneous fluids may be needed if the bird is severely dehydrated (Fig 31.2).

Decontamination

Preventing absorption of the substance is an important step in treating a toxicosis.

DERMAL EXPOSURES

With light dermal exposures, the bird can be gently spritzed with a solution of mild liquid dishwashing detergent and warm water, softly rubbed and then spritzed with plain warm water to remove soap. This process can be repeated as needed, making sure all soap is removed.

A thorough bathing may be indicated with heavy exposures. Following the bath, the bird should be lightly patted dry, kept warm and monitored for signs of hypothermia. Removal of the toxicants from the feathers is contraindicated if the bird is seriously ill; always stabilize the patient first. With corrosive or irritating substances, the bird's skin should be monitored for redness, swelling or pain.

OCULAR EXPOSURES

With ocular exposures, the bird's eyes should be gently flushed with tepid tap water or with physiologic saline. The use of an eyedropper to gently administer the flush is recommended in small birds. Fluorescein staining and follow-up examinations are warranted with exposures to corrosive agents or if clinical signs of redness, pain or ocular discharge occur.

ORAL EXPOSURES

Dilution with milk or water in combination with demulcents is recommended in cases of corrosive ingestion. Close monitoring is recommended following ingestion of corrosive agents, which can lead to tissue necrosis and inflammation of the mouth, esophagus and crop. Severity of injury depends on the concentration and duration of contact.

Never induce emesis in a bird. Emesis is considered unsafe in birds, due to the potential of aspiration and ineffectiveness of emetic medications.10 Crop lavage may be considered with recent ingestion of toxicants (Fig 31.3). Contraindications to performing a crop lavage include ingestion of corrosive substances or petroleum distillates. With ingestion of corrosive agents, gastric lavage is not recommended.3,4 Instead, oral dilution with milk or water is preferred.^{3,4} Dilution is most effective if it is performed early. Sedation is recommended for frightened or fractious birds. Isoflurane or sevoflurane gases are the optimal anesthetic agents, and an endotracheal tube should be inserted during the process to prevent aspiration. To lavage the crop, body-temperature saline is gently flushed into the crop and aspirated repeatedly (3-4 times).10

Activated charcoal is considered a non-specific adsorbent that binds to many substances through weak forces, and prevents their systemic absorption. It is not an effective adsorbent for corrosive substances, petroleum distillates or heavy metals.3,4,6,15 Activated charcoal can be given to birds with a dosing syringe, an eyedropper or lavage tube, although extreme caution must be used to avoid aspiration. Dosage of activated charcoal in most species

Fig 31.4 | Psyllium is high in mucopolysaccharides and forms a slick mass that can sweep the digestive tract free of a multitude of toxins. Using more than 2% concentration can lead to gastro-intestinal blockage by this hydroscopic mass. Given with balanced electrolytes and dextrose it will simultaneously act to rehydrate the patient.

Fig 31.5 | Inexpensive pet carriers are often made from hardware cloth. This metal wire is always toxic to chewers as it is high in lead and zinc. This 27-year-old Amazon traveled safely in such a carrier its entire life. The owner was lucky this did not kill the bird.

is 1 g/kg (or 1-3 mg/g body weight).3,4

Cathartics are substances that enhance the elimination of activated charcoal, but should be used cautiously in birds. Cathartics can be added to solutions of activated charcoal, or premixed combinations are available. Never use cathartics when the bird is dehydrated. Bulking agents can be useful in removing small solid objects from the bird's gastrointestinal tract, such as lead paint chips. One half teaspoon of psyllium (Fig 31.4) mixed with 60 cc baby food gruel has been suggested as a bulking agent for birds, and can be administered with a dosing syringe or eyedropper. Use extreme caution to avoid aspiration. The mixture may be repeated to ensure complete removal of the objects. Peanut butter also has been recommended as a bulking agent.

The bird should be monitored closely during treatment. Routinely evaluate vital signs and the parameters most likely to be affected. Preventive measures such as gastric protection or antibiotics may be needed. Additional measures such as nutritional and hydration support are key components for full recovery. Daily maintenance fluid requirements in most birds are 50 ml/kg per day.1 It is extremely important to maintain the bird's nutritional requirements. Hospitalized birds eating voluntarily can be fed their normal diet. Tube-feed ill birds that are not eating, unless vomiting or delayed emptying of the crop is present.1 Good nursing care should be given until the bird completely recovers. The propensity for hypothermia in a bird that is ill for any reason should be considered and external heat and humidity provided as required.

Common Hazards

HEAVY METALS

Zinc

Sources of zinc include hardware such as wire (Fig 31.5), screws, bolts, nuts, and USA pennies. Pennies minted since 1983 contain 99.2% zinc and 0.8% copper and one penny contains approximately 2440 mg of elemental zinc.¹⁵ The process of galvanization involves the coating of wire or other material with a zinc-based compound to prevent rust. Owners often are not aware of galvanization on the wire used for making cages (Fig 31.6). Food and water dishes also may be galvanized and sufficient zinc may leak into the water or food to create toxicity.

(Ed. Note: In tracking cases of zinc toxicity over 7 years, computer records indicate that in 82 cases of zinc toxicity, approximately half of the clients denied any potential exposure of their birds to zinc or other beavy metal. The idea that a bird out of its cage is truly "supervised" is overrated. Also, powder-coated cages made outside of the USA, especially in China, have been known to use zinc to expedite setting of the powder coating [F. VanSant, personal communication, 2000]).

Although the exact toxicologic mechanisms of zinc in birds or other animals is not known, zinc toxicosis can affect the renal, hepatic and the hematopoietic tissues. Clinical signs of zinc toxicosis in birds may include polyuria, polydipsia, diarrhea, weight loss, weakness, anemia, cyanosis, seizures and death.^{2,16} An underreported clinical sign of zinc toxicity is polydipsia with

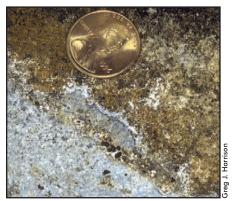

Fig 31.6 | Two sources of zinc: a USA 1cent coin and a galvanized metal cage tray. The zinc in the tray has oxidized to its most toxic form — a pure white powder evident at the margin of the rust and the galvanization.

Fig 31.7 | Placing a bird unanesthetized in a paper bag is often a safe and accurate way to diagnose metal toxicosis.

Fig 31.8 | Lead used to balance automobile wheels and fishing weights are modern sources of lead toxicosis.

passive regurgitation of water when the bird is handled. Mild anemia also is frequently encountered. Concurrent marked elevations in the total WBC are noted in the majority of cases of heavy metal toxicosis. Whether this is a true infection or an inflammatory response is not documented, so treatment with antibiotics will depend on the practitioner's evaluation. However, the presence of a high WBC should not convince the practitioner that the discovery of metal in the ventriculus is not the primary etiology of illness.

Diagnosis

Radiography of the abdomen may reveal the presence of metallic objects in the gastrointestinal tract. This need not be a properly positioned radiograph, but rather can be done as a stress-free scan for the presence of metal in the ventriculus (see Chapter 1, Clinical Practice for "bag rad" scan) (Fig 31.7). Serum zinc levels may be obtained using blood collected from plastic syringes (no rubber grommets) and stored in royal blue-top vacutainers or directly into vacutainers with appropriate needle to minimize contamination with exogenous zinc.15 In general, blood zinc levels of $>200 \mu g/dl$ (2 ppm) are considered to be diagnostic.16 The pancreas is considered to be the best tissue for postmortem zinc analysis. 2,16 Pancreatic tissue zinc levels greater than 1000 μ g/g are suggestive of a zinc toxicosis.16

Treatment

It is imperative to remove the sources of zinc from the gastrointestinal tract. Removal of zinc-containing foreign bodies via endoscopy or proventriculotomy/enterotomy may be required. The success of the removal process can be assessed with radiographs. Since most zinc items swallowed by pet birds are galvanized iron, the use of magnets attached to an enteral tube is an effective means of removing ferrous items that are zinc coated12

(see also Chapter 14, Evaluating and Treating the Gastrointestinal System). Activated charcoal is not indicated, as it is of little benefit in binding zinc.15 Bulk cathartics, psyllium (sodium sulfate 125-250 mg/kg), peanut butter, mineral oil and corn oil may aid in the removal of zinc objects from the GI tract. The use of chelators may not be necessary in cases where prompt removal of the zinc source is accomplished. If chelation therapy is instituted, careful monitoring of renal parameters is important for the duration of therapy. Elevated uric acids in heavy metal poisoning and a decrease with therapy have been reported (E. Odberg, personal communication, 2001). The following chelating agents have been suggested for zinc poisoning in birds: Ca EDTA 35 mg/kg BID, IM for 5 days.7 If needed, the second course of therapy is given after a 5- to 7-day waiting period. If/when the bird is able to tolerate oral medication, Dpenicillamine (Cuprimine) can be administered orally at 55 mg/kg BID PO for 1 week.7 A second course of 1week therapy can be given, if needed, after a 1-week rest. Succimer, (2, 3 dimercaptosuccinic acid) at 25 to 35 mg/kg for 5 days per week for 3 to 5 weeks also has been used to treat zinc toxicosis in birds.7 In addition, treatment for symptomatic animals should include blood replacement therapy as needed, parenteral fluids and good nursing care such as force-feeding or hand-feeding.

Lead

Sources of lead include paint, toys, drapery weights, linoleum, batteries, plumbing materials, galvanized wire, solder, stained glass, fishing sinkers (Fig 31.8), lead shot, foil from champagne bottles and improperly glazed bowls. 4,16 Lead is considered to be the most commonly reported of avian toxicosis with acute toxicities more common in captive birds and chronic in free-ranging birds (Fig 31.9).

Fig 31.9 | Pelicans are presented with fishing lines and hooks swallowed or tangled in their extremities. Radiographs for lead are always indicated to ensure a bird with a lead weight in its digestive system is not released.

Fig 31.10 | Peregrine falcons are carnivorous and can consume prey that were shot with lead-containing pellets. Radiographs are indicated.

Fig 31.11 | Blue-winged teal and other water birds can dabble in tidal marshes or ponds that may contain decades-old hunting remnants from lead shot.

Raptors can ingest lead shot from preying on animals that have been shot with or have ingested lead shot (Fig 31.10).²⁰ Lead toxicosis also has been documented in an Amazon parrot that had been fed portions of game birds that contained lead shot.¹⁸ Between 1983 and 1986, the National Wildlife Health Center examined 1041 moribund or dead waterfowl and diagnosed lead poisoning in approximately 40% (Fig 31.11).⁵ Although lead shot has since been banned for hunting waterfowl, spent shot is still present in waterways.²⁰ Ingestion of 1 to 3 lead shotgun pellets has been reported to be lethal to waterfowl.⁴

Lead affects multiple tissues, especially the gastrointestinal tract, renal and nervous systems. Lead combines with erythrocytes in circulating blood, increasing RBC fragility, anemia and capillary damage. It also can cause segmental demyelination of neurons and necrosis of renal tubular epithelium, GI tract mucosa and liver parenchyma. Clinical signs seen in psittacine birds are often vague and may include lethargy, weakness, anorexia, regurgitation, polyuria, ataxia, circling and convulsions.⁴ In some species such as Amazons, hemoglobinuria also may be noted.¹¹

Diagnosis

Radiography of the abdomen may reveal evidence of metal in the ventriculus. Blood levels of lead are helpful in confirming lead toxicosis in birds with suspicious radiographic changes. ¹⁹ Whole blood levels greater than 0.6 ppm are viewed as diagnostic for lead toxicosis when accompanied by appropriate clinical signs. ¹⁹ The basophilic stippling and cytoplasmic vacuolization of red blood cells are not always seen with lead poisoning in avian species. ¹⁹

Treatment

Removal of lead particles via bulk diet therapy, endoscopy or surgery is recommended. Succimer and Ca EDTA are both considered to be effective chelating agents in avian species. Succimer has been reported to decrease blood lead concentration by 87% when given at a dose of 30 mg/kg PO BID for 7 days minimum, with no apparent adverse secondary effects, however, a dose of 80 mg/kg resulted in death. The therapeutic dose of succimer in pet birds is 25 to 35 mg/kg PO BID 5 days a week for 3 to 5 weeks. Calcium EDTA is considered the preferred initial chelator for lead toxicity in birds and is given at a dose of 35 mg/kg BID, IM for 5 days, off 3 to 4 days, and repeated if needed. Fluid therapy is recommended to prevent renal effects from Ca EDTA during treatment. Penicillamine and diethylene triamine pentaacetic acid (DTPA) have also been used to treat avian lead toxicosis.

Since lead can be immunosuppressive, broad-spectrum antibiotics may be indicated.⁴ In addition, good supportive care including seizure control is recommended until full recovery.

Nicotine Products

Tobacco products contain varying amounts of nicotine (Table 31.1), with cigarettes containing 3 to 30 mg and cigars containing 15 to 40 mg. ¹⁵ Butts contain about 25%

Table 31.1 | Nicotine Content of Common Sources of Nicotine

Nicotine Product	Nicotine Content
Cigarettes	3-30 mg per 1 whole cigarette
Cigarette butts	.75-7.5 mg
Cigars	15-40 mg
Moist snuff	4.6-32 mg/g
Dry snuff	12.4-15.6 mg/g
Chewing tobacco	2.5-8.0 mg/g
Nicotine gum	2-4 mg per piece
Transdermal patches	15-114 mg per patch
Nicotine nasal sprays	10 mg per ml
Nicotine inhaler rods	10 mg per cartridge

of the total nicotine content. Nicotine also is found as a natural form of insecticide. Signs develop quickly in most species, usually within 15 to 45 minutes, and include excitation, tachypnea, salivation and emesis. Muscle weakness, twitching, depression, tachycardia, dyspnea, collapse, coma and cardiac arrest may follow. Death from nicotine toxicosis occurs secondary to respiratory paralysis.15 A less serious but common response to cigarette smoke deposition on the feathers is feather-destructive behavior.

(Ed. Note: One timneh grey that expired at 21 years of age reportedly had lived its entire life with a heavy smoker. The histopathologic diagnosis of multiple masses in the lungs was carcinoma, but was not definitely labeled as bronchiogenic).

Inhalants

The avian respiratory tract is extremely sensitive to inhalants. Any strong odor or smoke could potentially be toxic (Table 31.2).17 Polytetrafluoroethylene (PTFE)coated cookware or cooking utensils can emit toxic fumes when overheated (>280° F).17 Clinical signs may include acute death, rales, dyspnea, ataxia, depression and restless behavior.^{2,10} Hemorrhage and edema in pulmonary tissues leads to respiratory failure and death. Prognosis is usually guarded to poor. Treatment for inhalation toxicosis includes the administration of oxygen, rapidly acting corticosteroids, diuretics, analgesics, parenteral antibiotics and topical ophthalmic antibiotic ointment.1 A bronchodilator may be needed for bronchospasms1 (see Chapter 7, Emergency and Critical Care for an updated therapy). In most cases, prognosis is guarded to poor.*

*Ed. Note: The first-time heating of several new nonstick pans is a frequent finding with PTFE toxicosis. One empirical report (Beckett, personal communication, 2001) had a bird indirectly exposed days later when a wooden perch had been "sterilized" on a PTFE-

Table 31.2 | Examples of Noxious Inhalants

- · Some non-stick surfaces (pots, pans, cookware, irons, ironing boards)
- · Heating elements on reverse cycle air conditioners
- Gasoline or other volatile gas fumes
- Any source of smoke
- Automobile exhaust
- Carbon monoxide
- · Self-cleaning ovens and drip pans for ranges
- Aerosol sprays
- Cleaning products such as ammonia or bleach
- Paint fumes
- Fumigants
- · Candles with lead wicks, scented plug-in items

coated metal cooking sheet and the perch was then later placed in the bird's cage.

AVOCADO (Persea americana)

The toxic principle in avocado is persin, and leaves, fruit, bark and seeds of the avocado have been reported to be toxic to birds and various other species. 10,15,17 Several varieties of avocado are available, but not all varieties appear to be equally toxic. In birds, clinical effects seen with avocado toxicosis include respiratory distress, generalized congestion, hydropericardium, anasarca and death. 10,17 Onset of clinical signs usually occurs after 12 hours of the ingestion, with death occurring within 1 to 2 days of the time of exposure. 10 Small birds such as canaries and budgies are considered to be more susceptible, however, clinical signs have been observed in other species. Treatment for recent avocado ingestion includes decontamination via crop lavage and activated charcoal; bulking diets may help prevent absorption. Close monitoring for cardiovascular and pulmonary signs should follow. With symptomatic animals, treatment with humidified oxygen and minimal handling may be required. Diuretics may be helpful in cases with pulmonary edema.4

POISONOUS PLANTS

The following is a partial list of plants that have been shown to cause toxicity in small animals. The severity of signs or toxicity of these plants in birds has not been thoroughly studied.

Potentially Cardiotoxic Plants

- Lily of the valley (Convallaria majalis)
- Oleander (Nerium oleander)
- Rhododendron species
- Japanese, American, English and Western yew (Taxus spp.)
- Foxglove (Digitalis purpurea)
- Kalanchoe species
- Kalmia species

Plants That Could Cause Kidney Failure

• Rhubarb (Rheum spp.) - leaves only

Plants That Could Cause Liver Failure

- Cycad, Sago, Zamia palms (Cycad spp.)
- Amanita mushrooms

Plants That Can Cause Multisystem Effects

- Autumn crocus (Colchicum sp.)
- Castor bean (*Ricinus* sp.)

Plants Containing Calcium Oxalate Crystals

Peace lilies, Calla lilies, philodendrons, dumb cane,

Fig 31.12 | Houseplants need to be considered as potential toxicants, especially in birds with livers stressed by nutritional disorders.

Fig 31.14 | A lantana plant in the same aviary as in Fig 31.13.

Fig 31.13 | A poinsettia plant growing wild in the rare species breeding aviary in Tenerife, Spain.

Fig 31.15 | A budgie has been oiled by an ill-informed owner.

mother-in-law, and Pothos plants contain insoluble calcium oxalate crystals. These crystals can cause mechanical irritation of the oral cavity and tongue of birds when plant material is ingested. Clinical signs usually include regurgitation, oral pain, dysphagia and anorexia. The signs are rarely severe and usually respond to supportive care.

- Peace lilies (Spathiphyllum spp.)
- Calla lily (Zantedeschia aethiopica)
- Philodendron (Philodendron sp.)
- Dumb cane (Dieffenbachia sp.)
- Mother-in-law plant (Monstera sp.)
- Pothos (*Epipremnum* sp.)

(Ed. Note: A common presentation in cockatiels appears to be oral irritation from ingestion of small amounts of Pothos or philodendron species of plants (Fig 31.12). In this editor's practice, more than 15 cockatiels have presented over the course of 20 years with documentation of recent chewing on leaves of these plants and almost immediate production of clinical signs. The birds appear acutely depressed and anorectic, but still in good body weight. Examination of the tongue will reveal pronounced erythema, sometimes with obvious ulceration, and hypersalivation. Supportive care for 24

to 48 hours has resulted in 100% recovery. Lack of mortality also has lead to a lack of histopathology, so any additional toxic effects other than oral irritation have not been documented [TTL]).

Aviculturists need to be sure potentially toxic plants are avoided in the plantings of the aviary (Figs 31.13, 31.14).

OIL-CONTAMINATED BIRDS

Oil spills are not an uncommon problem for aquatic species of birds. According to California's Oiled Wildlife Care Network, bird survival is dependent upon many factors, including the speed of recovery and the species' susceptibility to toxicity and captive stress. The first step when treating oiled birds is to stabilize the animal and provide a warm (approximately 27° C) and stress-free environment. Common presenting clinical signs include respiratory distress and seizures. Following initial stabilization, a thorough exam should be performed. Most affected birds are hypothermic, hypoglycemic, hypoproteinemic and lethargic on presentation. Anemia also has been reported. Symptomatic care including nutritional support should be provided as needed.

Fig 31.16 | When presented to a rehabilitation center, an insectivorous raptor, the burrowing owl, should have pesticide toxicity investigated to document this common but seldom proven condition.

Fig 31.17 | The insectivorous passerine, such as this painted bunting, is seldom seen when ill. When presented for rehabilitation, pesticide toxicity should be investigated.

With oil contamination, feathers lose the ability to insulate, which can result in hypothermia¹ (Fig 31.15). Oil also can interfere with the animal's buoyancy.¹³ Oil can be removed from the feathers once the animal is stable using dishwashing detergent in warm baths. The temperature of water used should be 106° F, and water should be softened to 2 to 3 grains of hardness to help completely remove oil and prevent mineral crystallization in the feathers.¹³ Following thorough rinsing, the bird must be placed in a warm environment and allowed to dry. Multiple baths may be needed, however, repeat washings because of incomplete oil or soap removal are associated with increased mortality.13 Other recommendations for care include the use of lactulose at 0.3 ml/kg PO q 12 h, papaya enzymes, 1 tablet PO q 12 h, aggressive fluid therapy for feather-eating species and warmwater exercise pools.13

Editor's Comments

While documentation of environmental toxins is hard to prove as the cause of death in wild birds, one must strongly suspect pesticides when seeing insectivorous birds like burrowing owls (Fig 31.16), the painted bunting (Fig 31.17) and related birds presented to rehabilitation centers with clinical signs consistent with toxicity. When the literature on pesticides is studied (see reference 9 in Chapter 11, Low-Risk Pest Management), it seems rather obvious the veterinary profession is commonly missing pesticide toxicosis.

In 1999, a massive die-off of white pelicans (*Pelecannus erythrorhynchos*), wood storks (*Mycteria americana*), great egrets (*Ardea albus*) and great herons (*Ardea herodias*) occurred on the shore of Lake Apopka in Central Florida. The University of Florida and USA Fish and Wildlife eventually detected the chemicals DDT, toxaphene and dieldrin in lethal levels in these fish-eating birds. These pesticides are believed to be carcinogenic and were banned in the 1970s and 1980s; however, the chemicals can persist for decades in soil and animal tissue.

It was the nation's worst pesticide poisoning in decades. Over 800 documented great white pelicans were killed by this toxic exposure, and the extrapolated number of dead created great concern for the survival of this species in North America. However, political and legal concerns kept the problem from being widely publicized.

Pesticides have tremendous residual potential. Their prolonged half-lives, combined with the general lack of both infrastructure and funding for testing and detection of pollutants, make it likely that a great deal more exposures to toxic pesticides will occur in many species than is suspected or reported.

As veterinarians, we have an opportunity to be cognizant of this dangerous potential, to appropriately diagnose and treat these toxicities in individual birds, and also to report suspected toxicities to responsive authorities, requesting and expecting an appropriate investigative response.

Implications of

Viruses

in Clinical Disorders

DAVID N. PHALEN, DVM, PhD, Dipl ABVP

The past 15 years have seen remarkable growth in the understanding of the viral diseases of companion and aviculture birds. Molecular-based and traditional investigative and diagnostic tools allowed scientists to discover and understand the biology of many of the viruses that cause the common diseases seen in these birds. This information resulted in the development of management strategies that, when implemented, mitigate or completely eliminate the risk of several viral diseases. Unfortunately, we still lack critical information on a number of viral diseases and diseases thought to be caused by viruses. Additionally, not all bird owners are aware that they should apply what has been learned, and many are unwilling to do so. Therefore, viral diseases are still a significant threat to captive populations of birds.

Diagnostic Assays Used to Detect Viral Infections

SEROLOGY IN THE LIVE BIRD

Historically, serologic assays were used to screen large groups of animals to determine if a disease agent was present in the flock or herd in question. If a significant number of animals tested positive, then there was sufficient proof that the infectious agent was present and management changes were made accordingly. We ask much more from serology in pet bird and aviary medicine. We ask that each assay applied to a single sample tell us if the bird is or is not currently infected with whatever agent we are interested in; unfortunately, this is often not possible. Birds in the early stages of infection may not have had time to develop antibody. Assays that detect immunoglobulin M (IgM) will not become

positive for 7 to 14 days after infection, while assays that detect immunoglobulin Y (IgY) may take an additional 7 days before they are positive. The other major limitation of serology is that many birds remain seropositive after they are no longer infected with the virus and, without proper knowledge, a practitioner or bird owner could be misled into believing that a serologically positive bird was actively shedding virus.

Sadly, it must be noted that serologic and other diagnostic assays for avian infectious diseases have been and are still being offered commercially that are meaningless or their meaning is not known. For a diagnostic assay for any infectious disease to be valid, it must be tested rigorously in controlled infection trials or by the compilation and careful analysis of clinical data obtained from naturally infected animals. The accuracy of assays that have not been presented and preferably published in a peerreviewed journal is suspect until proven otherwise.

Enzyme-linked Immunoassay (ELISA)

The ELISA detects antibodies from test plasma that react with viral antigens. To do this, the assay depends on a specific secondary antibody that can recognize the antibody of the bird being tested. If a single species is being tested and a secondary antibody to that species is available, the ELISA is an excellent assay. Cross-reactivity between secondary antibodies made to the antibody of one species of bird and the antibodies of other birds, however, will vary. Therefore, an ELISA using anti-Amazon parrot antibody may work for all species of Amazons and with careful controls may be applied to all species of parrots. It is, however, not likely to work in divergent species, such as passerines or ducks.

Hemagglutination Inhibition Assay (HI)

Several avian viruses, including the psittacine beak and feather disease virus, avian influenza and the paramyx-oviruses, when added to red blood cells of the appropriate species will cause them to agglutinate. If the viruses are mixed with diluted serum containing antibodies to that virus, hemagglutination may be inhibited. HI can then be used to detect and quantitate circulating antibody. This assay is highly sensitive; however, non-specific hemagglutins and hemagglutin inhibitors occur in the serum of birds, complicating this assay. At times this assay may prove cumbersome, as some viruses will agglutinate the cells of some species and not others. If the necessary species are rare, this assay becomes impractical. Evidence suggests that the HI may not detect antibody in birds chronically infected with paramyxovirus 3.

Virus Neutralization Assay (VN)

The VN is a very sensitive and specific assay and can

detect both IgM and IgY as long as they are neutralizing. In this assay, serum or plasma is diluted and each dilution is incubated with a specific concentration of live virus. The virus-serum mixture is then incubated with cells that are susceptible to infection. The cells are monitored for several days. If antibody is present in the serum and neutralizes the virus, cytopathic effects (CPE) to the cells are prevented. If the serum does not contain antibody, CPE occurs at all dilutions of serum. The antibody titer is defined as the reciprocal of the highest serum dilution that results in a 50% or 100% reduction in CPE.

The biggest disadvantages of the VN are that it requires that live cells be available and the assay itself takes 3 to 5 days. As a result, most laboratories will do this assay only once a week, and the turnaround time may be as long as 2 weeks.

POLYMERASE CHAIN REACTION (PCR) IN THE LIVE BIRD

PCR has been the single most important advancement in the detection of subclinical virus infection of birds. PCR detects viruses by amplifying a portion of the viral DNA, or viral RNA converted to DNA, to detectable levels. Blood, oral and cloacal swabs, tissue swabs and even environmental swabs can be used in this assay. Which samples need to be examined for each virus will depend on the virus and the stage of infection at the time of sampling. Development of a PCR assay requires knowledge of the DNA or RNA sequence of the virus to be detected. It also is necessary to know the variations in the sequences of the specific viruses. If there is considerable genetic variability but little biological variation within a virus, it may be critical to develop an assay that can detect all of the viruses. On the other hand, if significant biological variation is correlated with genetic differences, it may be important to develop multiple PCR assays that can differentiate among the genetic variants.

PCR assays are highly sensitive, but not all PCR assays are equally sensitive. When screening birds for avian polyomavirus, psittacid herpesviruses and the psittacine beak and feather disease virus, it is important to use PCR assays that have the highest level of sensitivity. The most sensitive assays typically use a nested or semi-nested PCR reaction that produces labeled amplification products that can be detected with an automated system. The sensitivity of the PCR assay also can be a disadvantage. Contamination of the sample at the time of collection or at the laboratory can result in false-positive results. It takes contamination with only one infected cell to cause a sample to become positive. Contamination is much more likely to occur when multiple birds are sampled. This technology is rapidly advancing, and it is certain

that the ability to screen for many more diseases soon will be available. Likewise, the cost and convenience of these assays will greatly improve.

POSTMORTEM DIAGNOSTICS FOR VIRAL INFECTIONS

Many viruses leave a characteristic histologic pattern of disease in their victims. Therefore, if the whole bird or a complete set of fixed tissues is submitted to the pathologist, a diagnosis can often be made based on the presence of specific histologic lesions, such as patterns of necrosis, the inflammatory response and the presence of viral inclusion bodies. When inclusions cannot be found or the inclusions are not specific, macerated fresh tissue and even formalin-fixed tissue can be examined for virus particles using electron microscopy. Virus isolation sometimes is necessary to detect specific viruses. Viruses can be isolated in embryonated chicken eggs and in primary cell cultures. Virus isolation often requires multiple blind passages before the virus is detected, and the whole process may take one to several weeks. Not all viruses grow readily in eggs or cell culture, so a negative finding does not conclusively rule out the possibility of a viral infection.

Molecular-based diagnostic assays have greatly improved the pathologist's ability to detect infectious agents in necropsy specimens. Fresh tissues from birds that die with viral infections typically contain high concentrations of virus. This virus is readily detected by PCR, if an assay for that virus is available. Formalin-fixed tissues also can be examined for virus DNA. However, formalin degrades DNA into small pieces; therefore, it is best to screen tissues that have been fixed for only a short time or have been fixed and then imbedded in paraffin within 2 or 3 days. Selecting PCR primers that amplify a short segment of the viral DNA also will increase the chance of detecting the viral DNA in formalin-fixed tissues. In situ hybridization and in situ PCR are techniques where the viral DNA actually can be detected in thin sections of formalin-fixed tissues. These assays have only limited availability and have a reduced sensitivity as compared to PCR of fresh tissue; however, they have important applications under some circumstances.

DNA Viruses

CIRCOVIRUS: PSITTACINE BEAK AND FEATHER DISEASE VIRUS (PBFDV)

Applied Biology

PBFDV is a non-enveloped DNA virus. Its single-stranded genome appears to code for seven proteins. Multiple

variants of this virus have been identified, and the DNA sequence of these variants differs up to 11% compared to the originally sequenced variants. Studies in Australia have not shown a host specificity for any one of these variants or an indication that one variant is more pathogenic than others. Work in the USA has identified a variant that is commonly found in lories and lorikeets. The biology of this virus in lories may differ somewhat from other PBFDV variants in other species. Genetic variation in these viruses has significant implications for testing. In order to detect all PBFDV variants, PCR assays must be designed to detect conserved areas of these viruses that are identical in all of them. Alternately, multiple assays that are variant-specific must be used. The sequence of these viruses assays that are variant-specific must be used.

Infected birds shed virus in feather and skin dander, feces and crop secretions. Transmission has been postulated to result from inhalation of the virus, ingestion of the virus or possibly by movement of the virus across the bursal follicular epithelium. Vertical transmission also has been postulated; however, the overall role that vertical transmission plays in the dissemination of beak and feather infection remains uncertain. Naturally occurring disease predominates in juvenile and young adult birds. Whether birds become persistently infected and develop disease depends on the age and species of the bird exposed and possibly the specific variant of the infecting virus.

Virus replication occurs in a wide range of tissues, including the thymus, bursa of Fabricius, crop, esophagus, intestine, skin and feathers. Virus also has been identified in circulating leukocytes. Feather dysplasia results from virus-induced necrosis and disruption of the epidermal collar, intermediate basal epidermis and feather pulp, and thrombosis and hemorrhage within the feather pulp. Damage to the germinal epithelium of the beak is similar, resulting in the observed gross changes. Necrosis of the bursa, thymus and possibly circulating leukocytes results in varying degrees of immune suppression. Diseases caused by opportunistic pathogens are common in PBFDV-infected birds.³⁶

Clinical disease may develop within 2 to 4 weeks in exposed nestling parrots, but prolonged incubation periods of months and possibly even years are more likely when young adult birds are infected. Virus can be detected in the blood before clinical signs are observed. In one report, virus could be detected in an experimentally infected bird 2 days after infection. The onset of viremia may be longer in naturally infected birds.

Clinical Presentation

Species Distribution

Psittacine beak and feather disease (PBFD) occurs in a wide range of wild and captive parrots, particularly the

cockatoos, eclectus parrots (*Eclectus roratus*), budgerigar (*Melopsittacus undulatus*) and lories and lorikeets from Australia, the Pacific Islands and Southeast Asia. African parrots, including the African grey parrot (*Psittacus erithacus*) and lovebirds (*Agapornis* spp.), also are highly susceptible to infection and disease, and infection has been found in the wild African parrots. Infection in Neotropical parrots in captivity occurs at a low to moderate rate, but disease is rare. A small number of macaws and Amazon parrots and a single pionus parrot have been reported with PBFDV.²⁴ PBFDV infections in wild Neotropical parrots are not documented.

Signs in Cockatoos

PBFDV causes chronic progressive disease in birds older than 8 to 10 months. The large majority of birds with the chronic form of PBFDV first develop lesions between 6 months and 3 years of age. The first signs of PBFDV are subtle. A lack of powder on the beak may be the first indication that powder down feathers are diseased. Some birds will present with a history of a delayed molt. Close inspection of these birds will generally reveal at least a few dysplastic feathers. Both down and contour feathers are affected, but the disease may predominate in one or the other. Initially, diseased feathers are widely scattered and are associated with the pattern of molt. As the disease advances, all feather tracts will become involved, generally in a somewhat symmetrical fashion (Fig 32.1). In advanced cases, only down feathers, a few scattered contour feathers or no feathers at all may remain.

Affected feathers show varying degrees of dysplasia. Hyperkeratosis of the feather sheath is common, resulting in sheath thickening and retention. Growing feathers are short and may be pinched off either at their proximal ends or near their base (clubbing). Thinning of the rachis and recent and previous hemorrhage within the feather shaft is common. In some feathers there is so much disruption of feather growth that the sheath contains only a disorganized mass of keratin. Mildly affected feathers may show bowing, have transverse dystrophic lines and fracture at any location along their length.

Beak lesions are common in the sulphur-crested (Cacatua galerita), Major Mitchell's (C. leadbeateri), Moluccan (C. moluccensis) and umbrella cockatoos (C. alba), little corella (C. sanguinea) and galahs (Eolophus roseicapillus). They are less frequent or entirely absent in other species. These lesions may occur at any stage of the disease but are seen most commonly in birds with advanced disease. Early changes in the beak are the result of hyperkeratosis of its superficial layer. These changes cause beak elongation and overgrowth. Longitudinal fissures develop subsequently. In the terminal stages of the disease, the distal portion of the beak will

fracture, leaving underlying necrotic debris and bone. Necrosis of the palatine mucosa causes it to separate from the beak (Fig 32.2). The resulting space fills with caseous material. Beneath the caseous material is bone. These lesions are painful and birds may become partially or completely anorectic. Secondary infections of the beak and oral cavity are common. A pathologic process similar to the one occurring in the beak also may affect the nails of the feet. These lesions, however, generally are not a significant manifestation of PBFD.

If the beak lesions are not severe, birds can live with the PBFD for many years. However, the vast majority of these birds die, either from their primary lesions or from secondary infectious diseases within 6 to 12 months after onset of the signs. Mounting evidence suggests that birds with PBFD have significant alterations in their immune function. As a result, opportunistic pathogens, eg, yeasts and other fungi, both gram-positive and gramnegative bacteria, cryptosporidia and avian polyomavirus, are common complications and often terminal manifestations of PBFD. A survey of cockatoos with PBFD showed that most have high concentrations of avian polyomavirus in their skin and would be expected to be continuously shedding this virus.

Acute PBFD in nestling cockatoos may begin with nonspecific signs such as depression and regurgitation. Feather lesions develop rapidly and are extensive. These lesions may be identical to those seen in the chronic form of PBFD, or more often, annular constricting bands near the base of the feather develop simultaneously in numerous feathers (Fig 32.3). These feathers break off easily and may bleed. They also tend to be loose in the follicles and are easily pulled out. An understated feature of this disease is the discomfort of the nestling. The damaged feathers are painful and these birds do not want to be handled. Like the chronic form of PBFD, an early sign of infection is reduced powder on the beak. This last sign is not specific because young cockatoos do not always groom themselves as intensively as the adults and will routinely have less powder on their beaks. Advanced beak lesions rarely have time to develop, as the acute disease is often rapidly fatal. As with the older birds, the rate of disease progression varies. Infection studies suggest that rapidly fatal disease is likely to occur in umbrella and sulphur-crested cockatoos, whereas a more chronic form of the disease can be expected in galahs.

PBFD was rampant in wild-caught cockatoos imported into the USA and Europe prior to 1992. Importation has ceased or is dramatically diminished; as a result PBFD in cockatoos has become rare. Circumstances are entirely different in Australia, where the disease is common in the wild and infected wild-caught birds sold as pets.

Fig 32.2 | Necrosis of the junction of the rhinotheca and the oral mucosa in a cockatoo with advanced psittacine beak and feather disease.

Fig 32.3 | A nestling Moluccan cockatoo with the acute form of psittacine beak and feather disease. All growing feathers are involved. Many are seen to have hemorrhage within their shafts.

Signs in African Grey Parrots

Acute PBFD also occurs in juvenile African grey parrots. In experimentally infected birds, non-specific systemic signs preceded feather lesions. Dystrophic feathers identical to those seen in cockatoos also occur in African grey parrots. Additionally, newly formed contour feathers that would normally be gray will sometimes be red. Red coloration of contour feathers, however, is not specific for PBFD. Not all African grey parrots with PBFD have demonstrable feather lesions. A rapidly fatal form of PBFD was described in 7-week-old to 9-month-old African grey parrots. Birds typically presented with an acute onset of crop status, regurgitation and weakness. Feather loss was present in 3 of 14 birds. Total white blood cell counts fewer than 1000 cells/µl were common. An acute, often massive, liver necrosis also was a common finding, although changes in serum chemistry findings did not consistently correlate with the degree of liver disease. Most of these birds died or were euthanized within 2 weeks of presentation.^{36,37}

Signs in Lovebirds

PBFDV infection is extremely common in lovebirds. Up to 40% of the lovebird samples submitted to one laboratory for genetic probing were positive. A survey of commercial lovebird producers in Texas found that 60% of the facilities sampled had PBFDV in their collections. Many, possibly most, PBFDV infections in lovebirds do not result in clinical disease. The dynamics of PBFDV infection in lovebirds have not been studied extensively, but it appears that asymptomatically infected lovebirds

are only transiently infected. When disease does occur in lovebirds, it is most common in young adult birds. These birds appear unthrifty, they may shed feathers and not regrow them, or they may have a delayed molt. Dystrophic feathers may predominate, be scattered or absent entirely. Some of these birds survive for many months or years, and some will recover and may eliminate the virus. It has been reported that the lory variant of PBFDV may be common in lovebirds.

Encephalitozoon bellem is a common infection in lovebirds and a potential zoonotic disease. The prevalence of *E. bellem* shedding is significantly higher in lovebirds infected with PBFDV³

Signs in Budgerigars

PBFDV infection is enzootic in some budgerigar breeding facilities, but it is not as widely disseminated as it is in the lovebird. Most affected birds are fledglings. In the author's experience, diffuse feather changes similar to those seen in cockatoos are uncommon. Instead, many of these birds have normal feathering except for the complete absence of primary and secondary wing feathers (Fig 32.4). The owners refer to these birds as runners or creepers. These lesions are not specific for PBFD, and identical feather abnormalities are caused by avian polyomavirus infections. PBFDV and polyomavirus infections in budgerigars also can occur concurrently.

Signs in Eclectus Parrots

PBFD in the eclectus is very similar to that in the lovebird. Dystrophic feathers may or may not be present, but

Fig 32.4 | A budgerigar with "French molt." There is incomplete development of the primary wing feathers and the tail feathers. These lesions are the result of either psittacine beak and feather disease, avian polyomavirus or a concurrent infection with both.

feather quality of clinically affected birds is poor. Many of these parrots are unthrifty and are plagued with other infectious diseases. Fatal polyomavirus infections in adult eclectus parrots have been correlated with concurrent PBFDV infections.

Signs in Lories

PBFD appears to be relatively common in free-ranging Australian rainbow lorikeets (Trichoglossus haematodus). Fledgling lorikeets with typical dysplastic feather lesions are found walking on the ground. Histology of these birds reveals characteristic bursal lesions. Approximately one-third of these birds die before their first molt, another third have persistent feather abnormalities, but the remaining birds go on to molt and develop normal feathers (L. Filippich, personal communication, 1997). A similar disease has been described in lory and lorikeet collections in the USA. Some of these birds never develop signs, while others develop transient feather disease and still others develop persistent feather lesions and other manifestations of PBFD.35

Signs in Neotropical Parrots

PBFDV infection in New World parrots has been documented in 3 to 5% of samples submitted for PBFDV screening in one laboratory. Disease in these birds, however, is extremely rare. Clinically affected birds have feather lesions essentially identical to those of cockatoos. Also like the cockatoos, disease has been seen in both adult and nestling birds. Resolution of the clinical signs has been documented in some of these birds.

DIAGNOSIS

When typical clinical signs are observed, they strongly support the diagnosis of PBFD. PBFDV infection can be confirmed in birds with clinical disease, those with nonspecific signs and inapparently infected birds using a PCR assay of heparinized blood. In capable hands, this is a highly sensitive and specific assay. Birds with clinical signs of PBFD that are positive by PCR have a guarded prognosis. With supportive care, some will live many years with the disease. Uncommonly, clinical signs will resolve in some birds and they will subsequently become virus-negative. Birds infected with the lory variant may be more likely to survive infection. Histopathologic examination of biopsies from PBFD birds also can be used to confirm the clinical diagnosis. Clinically normal birds with a positive test result represent birds in the early stages of infection or birds with a transient subclinical infection or a sample that was contaminated at the time of collection. Clinically normal birds with positive test results should be retested in 90 days. Lories infected with the lory variant have remained positive for over 6 months without showing signs of disease. It is critical to remember that all positive birds are actively shedding virus whether they are showing signs or not. Also, birds that no longer have virus in the blood may continue to shed virus in their feather and skin dander until their next molt.

Before the PCR-based assay was developed, diagnosis of PBFD was made by histopathologic examination of plucked growing feathers or biopsies of feathers and feather follicles. Characteristic changes in the growing feather and its follicle and the presence of virus-induced intranuclear and intra-cytoplasmic inclusion bodies (basophilic globule cells) are considered diagnostic. Similar inclusion bodies are irregularly found in other tissues. In the African grey and eclectus parrots, feather lesions may not be present. In birds without feather lesions, the clinician often does not suspect PBFD. As inclusion bodies may be found only in the bursa, submission of a complete set of tissues is necessary for an accurate diagnosis.36

CONTROL

With the advent of a sensitive and specific diagnostic assay for PBFDV, control of this disease has been greatly simplified. All new birds should be tested for the virus at the time of purchase. Alternately, testing can be delayed a month to permit a recently exposed bird time to become viremic. The most conservative method would be to test initially after purchase and repeat the test in 30 days. Testing of new birds is of no value unless all other birds in the aviary also are tested. Although expensive, testing all birds in valuable collections of at-risk species can avert future catastrophic loses. Birds with a positive test result should be immediately removed from the aviary, as they are sources of massive amounts of virus.

The cost of testing individual birds can make it difficult to persuade pet store owners and private individuals to test all lovebirds and budgerigars. If private owners are unwilling to test these birds but have other birds at risk at home, they should be discouraged from keeping them. Rather than test individual birds coming into a collection, pet stores can require that their sources swab their aviary or holding areas for PBFDV before birds are purchased from them. PBFDV is believed to be highly resistant to commonly used disinfectants; therefore, aggressive cleaning is necessary to eliminate it from a contaminated environment. Following cleaning, PCR of environmental swabs can be used to determine if a facility has been adequately cleaned. Routine environmental testing in veterinary hospitals is recommended. A vaccine for PBFDV is not available at the time of this writing.

CIRCOVIRUS INFECTION IN THE CANARY

A disease with high morbidity and mortality has been reported in nestling canaries (Serinus canarius). Affected birds have a distended abdomen and an enlarged gall bladder. Exudate in the air sacs also is reported. Canary fanciers refer to the disease as "black spot," as the enlarged gall bladder can be observed through the nestlings' skin. Lesions characteristic of circovirus infections in other birds are present in these canaries, as are the characteristic intranuclear and cytoplasmic inclusion bodies. Diagnosis is most readily made in birds 10 to 20 days old. The partial DNA sequence of a novel circovirus — named the canary circovirus — was amplified from a flock of canaries experiencing a high degree of mortality. Gross lesions were confined to petechial hemorrhages in two of four birds examined. Microscopic examination of the tissues was not done. This sequence information will permit more extensive studies of this virus in the future.46

CIRCOVIRUS INFECTIONS IN COLUMBIFORMES

A circovirus infection also has been documented in pigeons. Unlike the disease seen in psittacine birds, it is not usually associated with abnormal feathering. Signs are rarely specific, and birds generally have other diseases as well. Chlamydophila, mycoplasma, adenovirus and herpesvirus infections and systemic bacterial infections have all been described in pigeons with circovirus infection. It is possible that this virus is immunosuppressive and weakens the pigeon's immune system to a point that other diseases develop⁴⁷ (see Chapter 13, Integument).

Diagnosis is made by finding basophilic globule cells in tissue sections. A complete set of tissues, including the bursa in the young bird, may be necessary to detect this virus by histopathology. This virus has been sequenced and a PCR assay capable of detecting the virus in tissue has been developed. Using this assay, it was shown that the Columbid circovirus, as it is now called, is widespread in European racing pigeons. It is highly likely that it is present in flocks of feral and domestic pigeons worldwide. Like PBFDV, Columbid circovirus also can be detected in the blood of live birds.¹⁴

AVIAN POLYOMAVIRUS (APV)

Applied Biology

APV is widespread and can be found in most countries of the world where psittacine birds are raised. It is a nonenveloped DNA virus that codes for six proteins. Some degree of genetic variation has been identified in APV but it is relatively small, and it is assumed that all APV variants have the same host range.²⁹ The route of natural infection has never been experimentally verified, but infection has been induced through the respiratory route. Given the rapid spread of this virus at bird sales and in the nursery, natural infection through the respiratory system is likely. In the budgerigar, the virus replicates in a wide range of tissues, including growing feathers, skin, liver, spleen, renal tubular epithelium, heart and cerebellum. Clinical signs and necropsy findings are largely associated with tissue distribution of virus replication. Disease in budgerigars is confined to nestlings. Not all budgerigars die with APV infection, and surviving birds shed virus in skin and feather dander and in droppings.²⁴

Most non-budgerigar parrots are assumed to be susceptible to APV infection. Disease, however, typically is limited to nestling parrots. Macaws, conures and eclectus parrots are over-represented, although diagnosis of this disease has occurred in most psittacine species (Fig 32.5). Birds become viremic sometime between 1 week and 10 days after infection. Disease, if it is going to occur, develops 10 to 14 days after exposure. It is characterized by generalized hemorrhage, moderate to massive hepatic necrosis, and an immune-complex glomerulopathy. Characteristic karyomegalic changes and intranuclear inclusion bodies are typically found in macrophages and other antigen processing cells, including the mesangial cells of the glomerulus. The vast majority of birds with these lesions die. Adult birds and nestlings that are infected but do not develop disease will remain viremic for a variable period of time and shed virus in their droppings, and possibly in feather dander and skin, before becoming virus-negative. Most infected birds clear the virus after several weeks to several months and, although they maintain a persistent antibody titer, are not thought to be persistently infected.30

Clinical Presentations

APV in Budgerigars

Budgerigar breeders first detect this problem in their flocks when there is a sudden increase in the number of dead nestlings in the nest boxes. The nestling mortality rate often is high and may approach 100% when the virus is first introduced to an aviary. If there is no intervention in subsequent breeding seasons, mortality rates will decline but production will always remain depressed. The signs of APV disease in budgerigar nestlings are somewhat variable. Most often, the young birds experience an abbreviated course of disease. At death, birds are found to be stunted and have abnormal feather development, skin discoloration, abdominal distension, ascites, hepatomegaly with localized areas of necrosis and scattered areas of hemorrhage. In some outbreaks, the virus attacks the cerebellum and these birds will have head tremors. Death predominates in birds that are 10 to 20 days old.25

Not every budgerigar nestling infected with APV dies. Some never show signs. Other nestlings will fail to develop their primary and secondary wing feathers and tail feathers (see Fig 32.4). These birds have been referred to as runners or creepers, and this form of the disease has been described as French molt. PBFDV or a combination of APV and PBFDV can cause identical lesions. It is possible that one or more additional diseases may cause similar feather disease. Not all budgerigars appear to be equally susceptible to infection and disease. In one study in the United States, English budgerigars were rarely found to be infected with APV, although they were housed with other birds shedding the virus.

APV in Non-budgerigar Parrots

Non-budgerigar parrots are susceptible to APV. Some are highly susceptible to disease, while others rarely, if ever, develop disease. APV disease in these birds occurs at different ages in different birds. In conures, deaths typically occur in birds less than 6 weeks of age. Deaths in macaws and eclectus parrots occur in birds 14 weeks and younger (see Fig 32.5). Most, possibly all, of the nestlings lost are being hand-fed. Infected nestlings appear healthy, show very few premonitory signs and then die suddenly. When signs do occur, they precede death by only a few hours. Observant owners may notice delayed crop emptying, weakness and a generalized pallor or bruising under the skin in the preceding hours before death. Yellow discoloration of the urates is another rare observation. Occasionally, complete blood count and serum chemistry tests can be performed prior to death. Increases in the liver enzyme aspartate aminotransferase are expected. Near death, birds have a marked thrombocytopenia. Birds that die are typically in excellent body condition. Additional findings commonly include generalized pallor with subcutaneous and subserosal hemorrhage and enlargement of the spleen and liver (Fig 32.6). Less commonly, ascites and pericardial effusion may be present.

APV in Lovebirds

APV disease in lovebirds is distinct enough to merit special attention. As in the budgerigar, this disease occurs in nestling birds, and inclusion bodies can be found in multiple organs. Unlike the budgerigar, birds up to 1 year of age also can be affected. This unusual age susceptibility has not been fully explained. However, in at least some of these older birds, concurrent infection with PBFDV also is occurring and may permit APV disease in a bird that would otherwise be resistant to it.

APV in Nestling Cockatoos

A unique presentation of APV disease occurs in nestling cockatoos. These birds present at an age of 4 to 8 weeks with a history of difficulty breathing. Physical examination reveals a severely dyspneic bird that is underweight and may be stunted in its growth. These birds have all the appearances of a bird that has aspirated food. Most of these birds die. Necropsy reveals heavy, wet lungs that may not float in formalin. Histologically, there is a severe generalized interstitial pneumonia with huge numbers of inclusion bodies in what are believed to be type II pneumonocytes. Preliminary sequence data suggests that this form of APV disease is caused by a specific APV variant. This variant is still capable of causing the classic form of APV disease in other susceptible species.³²

Post-APV Edema and Ascites Syndrome

Some birds that have APV disease survive. An unknown percentage of these birds go on to develop ascites and generalized edema. They still appear bright and alert and may continue to eat and empty their crops, but they are edematous and have a fluid-filled peritoneum. The fluid is a transudate or modified transudate and does not contain inflammatory cells. These birds do not improve and either die or are euthanized. Histologic lesions include a sclerosis of the glomeruli and regenerative lesions in the liver. It is suspected that the edema and ascites syndrome is secondary to hypoproteinemia, either from a failure of albumen production in the liver or a loss of protein from the kidney. Viral inclusion bodies are rare or absent in these birds. This disease very closely resembles the viral serositis lesions described in nestling parrots with eastern equine encephalitis and may be mistaken for it. These birds are still loaded with APV, and PCR of blood or cloacal swabs in the live bird or blood or a liver swab in the dead bird will be strongly positive.32

APV in Adult Parrots

APV readily infects adult parrots. Most infections, probably greater than 99.9% of them, are completely asymptomatic. These birds become infected, shed virus for a few weeks or do not shed virus at all, and do not show signs of illness. APV disease, however, has been documented in adult birds. Disease in these birds resembles that seen in the nestling. An atypical form of a progressive virus encephalopathy also has been reported in two cockatoos. Why rare adult birds or groups of birds develop disease is not known in all cases. In many cases, however, adult birds that die with APV disease have concurrent PBFDV infections. PBFDV is believed to be immunosuppressive, allowing APV to cause disease in a bird that would normally be refractory to infection. APV disease does uncommonly occur in adult parrots that do not have concurrent PBFDV infections. In the author's experience, these deaths typically occur in pet stores, suggesting that stress may play a role in the pathogenesis of disease.

Diagnosis

Testing Inapparently Infected Birds

The goal of testing is to detect inapparently infected birds that are shedding virus and to keep them from exposing other birds. Budgerigars, when infected as nestlings, shed virus for 6 or more months. Larger species of parrots, when infected as nestlings, become viremic for 4 to 8 weeks and shed virus from 6 to 16 weeks. Viremia and virus shedding have rarely been detected for as long as 10 months. Birds infected with PBFDV and APV may shed virus continuously. To detect virus-shedding birds, both blood and a combined oral and cloacal swab are examined by PCR. Testing blood alone is not recommended, as viremia ceases before virus shedding ends. Limited studies have been done on the duration of virus shedding in adult birds. However, it appears that after exposure, viremia and virus shedding are absent or greatly abbreviated as compared to nestlings. 25,28

All birds infected with APV develop a detectable virusneutralizing (VN) antibody titer within 2 to 3 weeks. The presence of antibody has no bearing on virus shedding, as antibody-positive birds continue to shed virus for many weeks. Also, once a bird develops antibody, most will maintain a high antibody titer many years after they have stopped shedding virus. Even though virus shedding cannot be predicted by serology, serology still has some value in the control of APV. Serology can be used to screen young budgerigars and lovebirds coming out of an aviary or returning from the show circuit. If they are coming from an aviary and are seropositive, they have been recently infected with APV and are most likely shedding virus. If birds that have been on the show circuit are seronegative after a 2-week quarantine, they are not infected with APV.

Postmortem Diagnosis of APV Disease

Gross and microscopic lesions seen in birds that die with APV infection are characteristic. Spleen, liver, lung and kidney are essential tissues to provide to the pathologist. These birds are viremic at the time of death, and swabs of any tissue will be positive by PCR. Immunofluorescent staining of impression smears and in situ hybridization also can be used to confirm infection if other histologic findings are inconclusive. ³⁶

Prevention and Control of APV²⁵

The key to prevention of APV disease is to make sure that birds that are shedding virus are not introduced into an aviary or that materials that might be contaminated with APV are not brought into the aviary. Testing can be an important part of a prevention plan. Excellent

PCR assays have been developed to detect infection in the live bird. Serology can be used to determine if a bird has been infected in the past but does not adequately predict the virus-shedding status of the bird.

Control in Budgerigar Aviaries

If a prevention program for APV infection is to be instituted in a budgerigar aviary, the first step is to make sure that it is not already there. The virus is readily detected by PCR in the environment of aviaries where the infection is enzootic. Alternately, blood and combined oral and cloacal swabs can be used to test nestlings and young adult birds. A virus neutralization assay can be used to detect antibodies to APV. Most birds in an aviary with enzootic APV will be seropositive.

Exhaustive efforts are required to keep APV out of a budgerigar collection. The movement of birds on and off the property must be carefully restricted. All new birds coming onto the property should be seronegative or PCR-negative. Alternatively, environmental swabs of their aviary of origin can be tested by PCR. If the aviary is a commercial aviary, dealers, feed salespeople, delivery trucks and other bird breeders should be banned from the aviary entirely. Young birds taken to the bird dealer and rejected should not be returned to the aviary. Food should be purchased directly from the feed mill so that it is never in contact with other birds. If the aviary is primarily breeding show budgerigars, then all birds going to the show should be quarantined until the end of the show season and tested by serology or PCR before they are returned to the breeding colony.

Budgerigars are not the only birds that can bring APV into a collection. Lovebirds and possibly cockatiels (Nymphicus hollandicus) also can be sources. Devastating outbreaks have occurred in budgerigar operations when lovebirds have been introduced into previously closed budgerigar colonies.

Elimination of APV from a budgerigar collection is challenging, but not impossible. The first critical step is to stop breeding. The infection cycle is perpetuated by the constant presence of infected nestlings, fledglings and young adult birds. These birds shed virus for up to 6 months or more after infection, seeding the environment with virus. Chicks are then exposed immediately upon hatch and the cycle continues. Once breeding is stopped, all birds that have not been used for breeding should be removed from the property. Adult birds should be moved to a temporary environment and the aviary totally disinfected. Nest boxes can be cleaned and painted but are better off destroyed and replaced with new boxes. All wood surfaces should either be discarded or cleaned and painted over. After a 6month hiatus, the adult breeding stock can be returned to the clean aviary and set up for breeding again.

Prevention and Control in Lovebird Collections

The sad state of the matter is that both PBFDV and APV are enzootic in many lovebird aviaries. Oddly, disease in these birds is often rare. Shedding, however, occurs in young lovebirds and may be continuous in birds that are concurrently infected with PBFDV. Breeders who wish to have a lovebird collection that does not have APV should first test their birds for infection. Again, serology using the virus neutralization assay or PCR of swabs from the environment or blood and combined oral and cloacal swabs of individual nestlings and fledglings will readily detect virus. To prevent the introduction of APV to a lovebird aviary, a representative number of each lot of incoming birds is tested by serology or PCR. Alternately, environmental swabs are used to verify that the aviary from which the birds originate is free of APV.

Prevention and Control in Aviaries Breeding **Non-budgerigar Parrots**

Outbreaks of APV do not occur in adult breeding birds, they occur exclusively in nurseries. Outbreaks occur when birds with inapparent infections, generally nestlings, are introduced to the nursery. If the following rules are followed, APV outbreaks in the nursery are extremely unlikely. Breeders of the larger species of parrots should not breed cockatiels, lovebirds or budgerigars. If they must breed these species, they must test them thoroughly to make sure they are not infected with APV. The breeder should raise only the chicks that they produce. If they must raise chicks from other sources, these birds must be quarantined and tested by PCR before they are brought into the nursery. Extensive and repeated environmental testing of the aviary of origin may be substituted for individual bird testing. Any bird that leaves the nursery and is in direct or even indirect contact with other birds must not be allowed back into the nursery. Adult birds coming into the aviary also should be quarantined and tested for APV. Ideally, people taking care of the nursery would not take care of the adult birds. Often, this is not possible. In these situations, cleaning up and changing clothes before working with the nestlings is recommended.

APV outbreaks in the nursery are devastating. In most cases, once APV is introduced to a nursery it spreads rapidly, so that by the time the first case is recognized most of the nestlings are already infected. This concept is important for two reasons. First, vaccination at this point will do no good. Second, testing during the outbreak will prove only that the virus is widely disseminated. To save money, the aviculturalist should be encouraged to reserve testing to determine when shedding has stopped and the chicks can be sold.

Little can be done to keep exposed chicks from becom-

ing infected with APV in most nurseries. However, efforts should be made to improve hygiene, decrease density of birds and use individual syringes for handfeeding individual chicks. The most important element in the control of APV outbreaks is to stop bringing babies into the nursery. Chicks can be left in the nest to be raised by the parents or pulled and sent to another facility to be raised. It remains unclear why, but parentraised chicks (excepting lovebirds and budgerigars) are not reported to develop APV disease. Surviving chicks will shed virus for 8 to 14 weeks, rarely as long as 16 weeks. The older the chick at the time of exposure, the shorter the period of virus shedding. Chicks should be negative by PCR of blood and a combined oral and cloacal swab before they are sold. PCR of the oral and cloacal swab is critical, as viremia ceases before shedding stops.

After the outbreak has stopped, a close inspection of the aviary must be done. Birds that might be shedding virus need to be identified and tested or eliminated from the aviary. Extensive cleaning and disinfection of the nursery also will have to be done. In aviaries where the underlying source of disease has been eliminated, subsequent breeding seasons can be free of the disease.

Preventing APV Disease in the Pet Store

The pet store is one of the most common places where APV outbreaks occur. Most pet stores get their birds from multiple sources. They sell budgerigars, lovebirds and cockatiels, the three species that are most likely to be shedding virus, and many stores will acquire susceptible species when they are still nestlings. To avoid disease, pet stores can use several strategies. The easiest and best method for preventing APV disease in the pet store is to buy only weaned nestlings. These birds will be old enough that, if infected with APV, they will not develop disease. If unweaned nestlings are to be purchased, they should be raised outside of the store until weaned. If nestlings must be in the store, they should be separated from all other birds, and have a person designated to take care of only them and no other birds. The public should not be allowed to handle these birds. Stores that sell high-value nestling parrots should consider limiting their bird sales to these birds only and not selling lovebirds, budgerigars and cockatiels. Establishing long-term relationships with breeders also can reduce the risk of disease transmission. Breeders supplying pet stores should be encouraged to develop a preventive medicine program to develop and maintain APV-free flocks.

Immunization

A commercial APV vaccine^a is available in the USA. Its value as a tool in the prevention of APV disease is controversial. The author's research has raised several ques-

tions about this vaccine and its ability to protect against APV infection. The vaccine is to be given to nestlings that are 4 weeks of age or older and is thought to provide protection to nestlings 2 weeks after the second vaccine, or by the age of 8 weeks. From the dynamics of the disease, however, most birds cannot be immunized early enough in life to be protected. An additional concern is that VN antibody was not detected in nestlings immunized with this vaccine, and immunization of adult birds resulted only in low antibody titers.²⁸ Clinical trials that claim to show that the vaccine stopped outbreaks of APV disease in nurseries did not study control flocks where the vaccine was not used. If new nestlings were not added to a nursery experiencing an outbreak, deaths would stop on their own within 2 to 4 weeks of the first death.³⁴ Claims that immunizing already infected birds will result in a shortening of the duration of virus shedding are not documented.

APV is, by and large, a completely preventable disease through appropriate management strategies and selective testing. As a result, the author stresses these avenues of control and does not recommend immunization.

APV Infection and Disease in Non-psittacine Birds

One or more APV strains can infect non-psittacine birds. Several species of passerines have been documented to have classical APV disease. In the author's experience, flocks of Gouldian finches (*Chloebia gouldiae*) are perhaps at greatest risk. Again in the author's experience, mortality is limited to nestling and young adult finches during one breeding season but is not seen again in the following year. Surviving birds have moderate levels of antibody that will neutralize a lovebird-derived APV APV DNA was detected in the tissues of one finch with PCR primers derived from the psittacine APV sequence, suggesting that this bird was infected with a psittacine variant. However, other studies suggest that another significantly different virus also may infect passerines.

There is a single published report of a rhamphastid dying with an APV disease. The bird was a green aracaris (*Pteroglossus viridis*). The virus sequenced from this bird was found to be nearly identical to those derived from psittacine birds. It was speculated that the original source was a cockatoo. In this study, in-contact birds, including zebra finches (*Poephila guttata*), a kookaburra (*Dacelo novaguineae*) and a Lady Ross turaco (*Musophaga rossae*), became seropositive but did not develop disease.¹⁹

APV Infection in Free-ranging Birds

There is strong evidence that APV infection occurs in wild birds on multiple continents. A high prevalence of anti-APV antibody was found in free-ranging greater

sulphur-crested cockatoos in Australia.33 APV disease has not been reported to occur in wild Australian birds, but a disease with characteristic APV lesions was induced in a cockatoo infected with a preparation of PBFD virus derived from the feathers of a wild bird, suggesting that APV was present in these tissues and was copurified with the PBFD virus.³³ Recently, APVs were identified in five buzzards (Buteo buteo) and a falcon (Falco tinnunculus) in Europe. Genetically, the sequence of the falcon virus was nearly identical to other APV variants of psittacine origin and the virus in the buzzard amplified with PCR primers derived from the sequence of the original APV isolated from a budgerigar. Because of autolysis in the buzzards, the histologic lesions associated with this disease could not be characterized.17

Preliminary evidence that APV may occur in wild birds in North America also exists. A house sparrow (Passer domesticus) was found to have a glomerulopathy with characteristic APV-like inclusions within mesangial cells and PAS-positive deposits within the mesangium and glomerular capillaries.²⁴

Goose Hemorrhagic Polyomavirus

A genetically distinct polyomavirus with limited homology to the avian polyomavirus has been implicated as the cause of the hemorrhagic nephritis and enteritis of geese in Europe. Little is known about the importance of this virus in waterfowl, but it may be widespread, as the histologic lesions that it is reported to cause are not specific.13

PAPILLOMAVIRUSES

Diseases caused by papillomaviruses in birds have been described only in wild European finches and imported African grey parrots. The African grey parrots had papilliferous plaques of the commissures of the beak, eyelids and face that became more extensive over the course of the year the birds were monitored. Lesions in European finches predominate on the legs and feet; lesions of the face are rare. These lesions should be differentiated from those caused by poxviruses.43

ADENOVIRUSES

Adenoviruses in Companion Birds

Adenovirus infections and disease in companion birds are rare. They have been associated with hepatitis, acute necrotizing pancreatitis, conjunctivitis and a multisystemic disease in lovebirds. However, recent reports of these diseases have been lacking. Adenovirus-associated encephalitis also is a rare disease that has not been recently reported. Characteristic basophilic intranuclear inclusion bodies are infrequently seen in renal tubular epithelial

cells in parrots that die with other diseases. These lesions are most common in lovebirds and budgerigars. 21,36

A fatal adenovirus infection causing hepatitis is described in the nestlings of Senegal parrots (Poicephalus senegalus) and related species. The disease occurs sporadically within aviaries. In one collection, the disease occurred in 3 out of 4 years in offspring from a single pair of Senegal parrots. Affected nestlings typically present acutely ill or are found dead. Grossly, the liver is discolored red-black, and scattered yellow-gray areas may be present. Multifocal hepatic necrosis and the presence of large, darkly basophilic intranuclear inclusion bodies within hepatocytes characterize this disease.36

The author has seen adenovirus infections in several mixed flocks of finches. Typically, clinical signs are not observed. Concurrent diseases, such as candidiasis and atoxoplasmosis, were common. Poor hygiene and high stocking density may have played roles in these deaths.

Pigeon Adenovirus

Adenoviruses in pigeons cause two distinctly different diseases. The first occurs in pigeons less than 1 year old and may be associated with the onset of the racing season. This virus replicates predominately in the intestinal epithelium, causing villus atrophy. Many birds will develop disease. Signs are those of acute severe enteritis, diarrhea and vomiting. Severely affected birds die, but many uncomplicated infections resolve within 1 week. A common complication of this adenovirus infection is an Escherichia coli overgrowth of the intestinal tract. These birds have persistent diarrhea, lose condition and will die if not aggressively treated. E. coli overgrowth of the intestine also can result in septicemia and sudden death. Mild to moderate hepatic necrosis may occur in some infections and contribute to the clinical signs and duration of the disease.

A second adenovirus causes massive hepatic necrosis. All ages of birds are susceptible. Disease, however, is sporadic in a flock and spreads slowly. Signs of infection include vomiting and biliverdin-stained urates; however, most birds die before signs are recognized. Birds showing signs die within 24 to 48 hours.

Diagnosis for both adenovirus infections can be made only at necropsy. Treating for dehydration and secondary bacterial infections can mitigate mortality in birds with the enteric adenovirus infection.8,52

PSITTACID HERPESVIRUSES (PsHVs)

Applied Biology

PsHVs are alpha herpesviruses that are the causative

agent of Pacheco's disease (PD) and internal papillomatosis of parrots (IP). The PsHV1 virus contains three major serotypes. Two additional serotypes (serotypes 4 and 5) are described, but they are each represented by only a single virus isolate. It is unclear if 5th serotype is a PsHV1 or an entirely different herpesvirus. There are four major genotypes of PsHV1. The viruses in genotypes 1 and 4 comprise serotype 1, the viruses in genotype 2 comprise serotype 2 and the viruses in genotype 3 comprise serotype 3. The single serotype 4 isolate is a genotype 4, but appears to have evolved into a unique serotype. 49 A new herpesvirus, PsHV2, has been discovered. This virus has been identified in mucosal tissues from Congo African grey parrots and a single blue and gold macaw. Most birds were not showing signs of disease, however this virus was found in a mucosal papilloma in one African grey parrot and cutaneous papilloma from another.

The study of the complexity of these viruses and the correlation between genotype and pathotype is still in its infancy, but patterns are beginning to unfold. Current sequence data has allowed the development of PCR primers that can detect all of the viruses discovered to date. This discovery allowed investigators to determine that the PsHVs that cause PD persist in the mucous membranes of the oral cavity and cloaca and can be inconsistently detected in the blood.^{31,49,50}

Based on these data, the following epizootiologic picture is proposed. Transmission between birds occurs when a naïve bird is exposed to the oral secretions, droppings or vomitus of a persistently infected bird. The route of infection can be by ingestion or contact with conjunctival or respiratory mucous membranes. The outcome of infection will depend on the genotype of the virus and the species of bird exposed. Genotypes 1, 2 and 3 are highly pathogenic to Amazon parrots. In Europe, genotype 4 PsHV also kills Amazon parrots, but this virus is not found to cause PD in Amazon parrots in the USA. 49 In contrast, genotype 4 is the most common cause of PD in macaws and conures. Cockatiels, cockatoos and other Pacific species of birds are relatively resistant to PD, but when they do develop disease, any of the four genotypes may be responsible. African grey parrots are susceptible to genotypes 2, 3 and 4. Genotype 1 has not been found in African grey parrots with PD, but the number of African greys tested to date is small, so this should be considered only a preliminary finding.

Birds that become infected with PsHVs and either do not develop PD or do develop PD but are treated and survive will become persistently infected and will remain persistently infected for life. There is a possibility that some subclinical infections may result in a cure, but this

remains to be proven. There is no evidence that persistently infected birds will subsequently develop PD. However, some persistently infected birds will develop IP. Which birds will develop IP may depend on the species of the bird, the genotype of the virus and as yet undetermined factors.

Most persistently infected birds are readily detected by PCR analysis of blood and combined oral and cloacal swabs. These birds will be consistently positive with repeated samplings.31 Even though PsHVs are continuously present in the mucosa of persistently infected birds, field data suggest that actual virus shedding or the degree of virus shedding may fluctuate over time. Species persistently infected with PsHVs include the macaws, Amazon parrots, some of the Aratinga conures and the Patagonian conure (Cyanoliseus patagonus). Increasing evidence also suggests that cockatiels, lovebirds, cockatoos and possibly other species may be persistently infected with one or more PsHVs. Wild-caught birds that have passed through a quarantine station, parent-raised chicks of wildcaught birds and birds that have survived an outbreak of PD are at highest risk for persistent infection.

The incubation period for PD typically ranges from 5 to 14 days. Virus replication occurs in a number of organs, and birds are viremic. Inclusion bodies are most often found in the liver and spleen and to a lesser extent the crop, small intestine and pancreas. Necrosis of the infected cells, particularly hepatocytes, accounts for the clinical signs.³⁶

Clinical Presentation

PD occurs almost exclusively in psittacine birds. Disease is most common in avicultural collections, quarantined birds and pet stores. The most common clinical presentation is a dead bird that died with little or no advanced evidence that it was ill. PD occurs most frequently in mixed collections of parrots that contain Amazons, macaws and conures, particularly Patagonian and Aratinga conures. The onset of the breeding season or recent changes in the aviary may predispose to virus shedding and PD outbreaks. Clinical signs may precede death in macaws and less frequently in other species. Signs are non-specific and include lethargy, depression and anorexia. Profuse sulfur-colored (biliverdin-stained) urates are another non-specific but consistently reported sign. Regurgitation, bloody diarrhea and terminal central nervous system signs are infrequently reported. Duration of clinical signs ranges from a few minutes to a few days. Only a few birds are known to survive infection once clinical signs develop. Elevation in the serum aspartate amino transferase concentrations and a marked leukopenia are reported in these birds. Radiographically, hepatomegaly, splenomegaly and renal enlargement also are

documented. The number of affected birds can vary from a single isolated case to hundreds.²⁴

To the author's knowledge, the only documented naturally occurring case of Pacheco's disease in a non-psittacine bird occurred in a keel-billed toucan (*Ramphastos sulfuratus*). Lesions in this bird and a second keel-billed toucan experimentally infected with Pacheco's virus were characteristic of the psittacine infection. In another toucan (species not reported), a disease resembling Pacheco's disease was described. Herpesvirus virions were identified in the tissues of this bird; however, fluorescent antibody-staining of the tissues with a Pacheco's virus-specific antibody was negative.

Diagnosis

Diagnosis in the live bird is difficult and rarely made. History, signs and laboratory findings are strongly suggestive of PD but are not specific. These birds are strongly positive on PCR of combined oral and cloacal swabs and blood but usually die before the samples can be analyzed. In the author's experience, once a bird is confirmed to have disease and owners know what to look for, they will detect the early stages of the disease in birds, often in time to save them with treatment.^{24, 36}

Most birds that die are well muscled and may have recently ingested food. Common gross lesions include hepatomegaly, splenomegaly, renal swelling and serosal and epicardial hemorrhage. The affected liver may be uniformly pale yellow, resembling the appearance of a diffuse lipidosis (Fig 32.7), have a diffuse mottling, or have scattered, irregularly shaped, discolored foci. In many birds, liver lesions are not observed grossly. Less commonly, submucosal hemorrhage of the intestines with or without intraluminal blood also may be present. Because of the acute nature of this disease, gross lesions may be entirely absent in some birds.

Histologically, hepatic necrosis is present in the vast majority of the cases. Varying degrees of splenic lymphoid hyperplasia and necrosis, pancreatitis and enteritis also occur. Eosinophilic and, less frequently, basophilic intranuclear inclusion bodies are found in the liver on the margins of the necrotic areas and in bile duct epithelium. Inclusions will sometimes be present in the spleen, intestinal epithelium, crop and pancreas. Although these lesions are characteristic for PD, the diagnosis can be verified by PCR of tissue swabs, staining impression smears with specific fluorescently labeled anti-Pacheco's virus antibody and in situ hybridization.

Treatment

Mortality in Pacheco's virus outbreaks can be minimized by prophylactic use of acyclovir^b. In the author's experi-

ence, mortality stops within 24 hours after the initiation of flock treatment. Treatment options include administration of acyclovir in the drinking water (1 mg/ml) and food (400 mg/quart of seed) simultaneously or by gavage (80 mg/kg q 8 h). A higher oral dose of 330 mg/kg q 12 h also has been recommended. The necessary length of treatment is not known. The author treats flocks for 7 days and birds with signs of disease for 2 weeks.²³

Preventing virus spread is another important aspect of bringing a Pacheco's disease outbreak under control. Traffic through the aviary should be minimized and hygiene improved. Additionally, barriers between cages can be erected, or cages can be moved farther apart. Intensive cleaning efforts may result in the increased aerosolization and further dissemination of the virus. Immunization in the face of an outbreak is of questionable benefit, as protective antibody titers would not be expected for 2 weeks after vaccination.

Prevention and Control

Control measures fall into three categories: savvy management practices, testing and immunization. Given that some conure species have repeatedly been implicated in the outbreak of this disease, these birds should not be kept in a mixed collection. General concepts, such as a closed aviary, proper quarantine procedures and acquisition of birds from reputable sources, will help to minimize the likelihood of Pacheco's virus being introduced to an aviary. Adequate spacing between cages and limiting human traffic in the aviary also are important preventive measures. Outbreaks are less likely to occur in outdoor aviaries.

Testing is becoming an increasingly practical means of preventing the introduction of PsHVs into a collection. Persistently infected birds are readily detected by PCR of blood and combined oral and cloacal swabs. Birds that are at highest risk for being persistently infected are those that have survived PD outbreaks and wild-caught parrots and chicks raised by wild-caught parrots. Macaws, Amazon parrots, Patagonian conures and *Aratinga* spp. conures commonly are demonstrated to be infected persistently.

A single Pacheco's disease virus vaccine^c is currently being marketed in the USA. The serotype of the virus in this vaccine and its ability to protect against all serotypes of PsHVs are not known. Immunizing parrots in mixed collections of high-risk birds may be beneficial.

Internal Papillomatosis of Parrots (IP)

Clinical Manifestations

IP is a disease that primarily affects macaws, Amazon parrots, hawk-headed parrots and, less commonly,

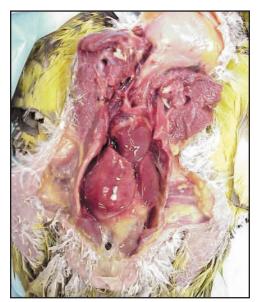

Fig 32.7 | An eclectus parrot with Pacheco's disease. The liver has a diffuse yellow mottling that is caused by extensive hepatic necrosis. Although many cases do not present with this lesion, the presence of this lesion should alert the practitioner or pathologist to the possibility that they are dealing with Pacheco's disease.

Fig 32.8 | Extensive papillomatous changes to the cloacal mucosa of an Amazon parrot.

conures. Most lesions are confined to the oral and cloacal mucosa, although lesions also may be found in the conjunctiva, nasal lacrimal duct, bursa, esophagus, crop, proventriculus and ventriculus. Cloacal lesions are the most common manifestation of IP in Amazon parrots and generally are present in the macaw as well. Oral papillomas are common in macaws. Of the macaws, the green-winged macaw (*Ara chloroptera*) is prone to develop the most widely disseminated form of IP. In these birds, lesions generally are present in both the cloaca and oral cavity and may extend into the esophagus, crop and even the proventriculus and ventriculus. Less frequently, blue and gold (*Ara ararauna*) and scarlet macaws (*Ara macao*) and, uncommonly, an Amazon parrot will develop this diffuse form of IP.²³

Owners usually first recognize that their bird has IP when they see blood in the bottom of the cage from an ulcerated cloacal papilloma or when the papilloma prolapses through the cloaca (Fig 32.8). Oral lesions may be extensive but rarely result in clinical signs. Papillomatous lesions are rarely static; they wax and wane and may disappear entirely. Often, the only indication that IP is present is a slight roughening of the cloacal mucosa or a thickening of the choanal edges and blunting of the choanal papillae. If the lesions do not spontaneously resolve, each time they recur they generally are more severe. The lesions in some birds will be consistently present. Birds with IP may live for many years and even be reproductively successful. The general life expectancy of these birds, however, is dimin-

ished as compared to other birds without this disease. The chronic irritation associated with cloacal lesions and repeated surgeries to remove the lesions may result in cloacal strictures. Birds with diffuse lesions of their upper digestive system often develop a wasting disease that may resemble proventricular dilatation disease.

A small to moderate percent of birds with IP will go on to develop bile duct or pancreatic duct carcinomas. Signs of bile duct carcinomas are not specific. Birds typically lose body condition, appear unthrifty and may have an overgrown beak. Elevated gamma glutamyl transferase levels have been reported in birds with advanced lesions. Bile duct carcinomas are readily demonstrated with ultrasonography and appear as hyperechoic round to irregular masses. Infection with PsHV genotype 3 may predispose to the development of bile duct carcinomas.

Treatment

Birds with cloacal papillomas are often in pain, so it has been common practice to remove all or part of these lesions. Cryotherapy, electrocautery, chemical cautery, laser surgery and sharp dissection have all been used. In the experience of the author, removing part of a lesion will often cause the remainder to regress; these lesions generally return, however. To minimize the risk of stricture formation, surgery is limited to a small portion of the cloaca or not done at all. Carboplatin has been used in a few birds to treat bile duct carcinomas (B. Speer, personal communication, 2001) (see Chapter 35, Surgical Resolution of Soft Tissue Disorders).

Prevention

Mounting evidence strongly suggests the viruses that cause PD are the same viruses that cause IP. 18,27,43,44,48 Depending on the genotype of the viruses and the species involved, however, these viruses can disseminate through a collection without causing Pacheco's disease. The first clue that the virus is there is when birds begin to develop papillomas. Transmission can occur from parent to offspring and between cages of birds. Transmission is much more likely to occur if cages are in close proximity and birds are housed indoors. A meticulous physical examination of birds before entry into a collection coupled with a PCR assay for PsHVs will detect infected birds.

Treating birds with anti-herpesvirus drugs will not cure them of infection and does not appear to impact the course of IP. These viruses presumably persist in a nonreplicating form and are not susceptible to these drugs.

Cutaneous Plaques and Papilliferous Lesions of the Foot

Herpesvirus virions are documented in proliferative lesions on the feet of macaws and cockatoos. These lesions show some species-specific variations. Lesions in cockatoos tend to be papilliferous, while those of macaws are raised, depigmented plaques. These lesions regress if treated topically with acyclovir. The sequence of a herpesvirus from a plaque from the foot of a macaw was found to closely resemble that of the PsHVs that cause PD and IP.48

MISCELLANEOUS HERPESVIRUS INFECTIONS IN COMPANION BIRDS

An infection resembling a herpesvirus infection is described in Gouldian, melba (Pytilia melba) and purple grenadier (Uraeginthus ianthinogaster) finches. Clinical signs include weight loss, anorexia, dyspnea, severe conjunctivitis and, less commonly, a head tilt. Mortality ranges from 25 to 100%. Gross and microscopic lesions are found in the conjunctiva, trachea and air sacs. 40

A herpesvirus has been isolated from English budgerigars in Europe. Its presence has been correlated with reduced hatchability and is believed to be transmitted vertically.

A virus believed to be a mutation of the infectious laryngotracheitis virus of chickens has been observed to cause a severe upper respiratory and tracheal disease in Amazon parrots and Bourke's parakeet (Neophema bourkii). The duration of this disease is variable, but clinical signs have been reported to last up to 9 months. This disease is reported in the USA, but if it occurs in the USA, it is rare. Additionally, tracheitis occurs uncommonly in some birds with Pacheco's disease, and this could be mistaken for Amazon tracheitis.

DUCK VIRUS ENTERITIS (DVE)

This herpesvirus has caused massive die-offs of wild ducks on several occasions in the USA. In Texas, the disease is seen on a smaller scale in the early summer on small community or golf course ponds. Generally, these ponds are densely populated with semi-domestic ducks. A common factor in most of the outbreaks is the presence of Muscovy ducks on the pond. There is a significant amount of controversy surrounding this virus and what to do when an outbreak occurs. In the past, attempts were made to euthanize all ducks on the pond in an effort to eliminate the carrier birds. This approach to control is rarely practical and almost certainly will offend some members of the local community. Additionally, genetic-based tests now support the idea that this virus is widespread in wild waterfowl. At this point, the best method of control is to limit the density of ducks maintained on ponds and, if possible, prevent the introduction of Muscovy ducks onto these ponds.38

PIGEON HERPESVIRUS (PHV)

PHV has a worldwide distribution and is a particular problem in racing pigeons, as birds are exposed when closely housed with birds from other lofts prior to each race. When the virus is first introduced to the loft, many birds will be affected. Signs include depression, reluctance to move, protrusion of the third eyelid, conjunctivitis, vomiting, rhinitis, dyspnea, anorexia, weight loss and loose green droppings. Characteristic gray to yellow oral and pharyngeal diphtheritic plaques mark this disease. Birds that survive infection appear to remain infected for life. Virus shedding increases during the breeding season, resulting in infection of squabs. Infected squabs become carriers but disease does not occur, possibly because of passive transfer of antibody.^{8,23} Egg transmission of PHV does not occur, and fostering eggs from infected flocks under hens that are not infected may break the infection cycle.²³

POXVIRUSES

Applied Biology

There are many poxviruses. Each poxvirus has its own host range, a range that may include one or several species of birds. Examples of poxviruses with a limited host range include the canary poxvirus, which affects only canaries and canaries hybridized with other species, and the parrot pox that appears to be confined to South American parrots. A mynah poxvirus appears to affect only mynahs, but mynahs may be susceptible to the starling poxvirus.24,51 In contrast, poxviruses brought into

Hawaii in non-native species have had a devastating impact on native Hawaiian forest birds. Fowl pox can cause disease in a number of gallinaceous birds and appears to be the cause of pox lesions seen in ostrich chicks in the USA.³⁹

Poxviruses require an injury to enter the body. Mosquitoes are the most common vectors for poxviruses, allowing the virus to enter the body through a bite wound. When wild-caught nestling blue-fronted Amazon parrots were held in quarantine, incompletely sanitized hand-feeding utensils were believed to spread the virus from one bird to the next. Generally, canary outbreaks occur in birds that are housed outdoors, but conspecific aggression and cannibalism also may result in rapid dissemination if latently infected birds are present in the flock. Rarely, aerosolized virus in feces or feather dander may directly infect respiratory epithelium.

Clinical Presentation

The practitioner is most likely to see this disease in canaries and chickens housed outdoors and in free-ranging birds and young domestic pigeons. Historically, disease was seen in nestling blue-fronted Amazon parrots held in quarantine. This problem is not seen in captive-raised birds and, because the importation of these birds has essentially ceased, this manifestation of disease is no longer seen in the USA.

Three forms of disease are recognized. The so-called dry pox is the most common disease manifestation. In this form of the disease, lesions are most commonly seen around the face (especially the eyelid and commissures of the mouth), on the feet and under the wings (Fig 32.9). Lesions are raised, smooth to nodular, and may ulcerate. Lesions may be small and clinically insignificant to extensive, deforming lids and even the beak. Extreme cases result in lesions that may appear neoplastic. Secondary superficial bacterial and fungal infections occur in ulcerated lesions. Conjunctivitis and keratitis are common when there is extensive lid involvement. Extensive lesions also may impair vision, resulting in the birds not being able to find food. The lesions develop rapidly over the course of several days, but take up to 6 weeks to regress. When they do begin to regress, they regress rapidly.

Wet or mucosal pox is a second manifestation of some poxvirus infections. It is seen in canaries, lovebirds, mynahs and imported blue-fronted Amazon parrots. The disease in canaries is characterized by a unilateral or bilateral blepharitis, chemosis and conjunctivitis. Typically, there will be considerable ocular discharge and the eyelids will swell shut. Diphtheritic lesions of the oral cavity and trachea develop subsequently. These lesions cause the birds to stop eating, and secondary

infections of these lesions are common. Extensive oral lesions and tracheal lesions may obstruct airflow and cause asphyxiation. Mortality in canary aviaries is often high. If treated aggressively, some of these birds will survive but may have persistent ocular lesions. Wet pox sometimes may accompany dry pox.

Systemic pox occurs in canaries as an acute onset disease. Chemosis, depression, anorexia and dyspnea characterize this disease. Birds die within a few days. If they survive, they will develop cutaneous lesions. Necropsy findings include air sacculitis and pneumonia.

Diagnosis

The gross appearance of the lesions in the appropriate species is highly suggestive of the disease. Biopsies of mucous membranes and cutaneous masses will reveal the classic large eosinophilic intracytoplasmic inclusion bodies (Bollinger bodies) (Fig 32.10). Impression smears of these lesions also may reveal these inclusion bodies. Because the lesions often ulcerate, inflammatory cells, bacteria and yeasts are likely to be present in scrapings and impression smears.

Treatment

The poxviruses themselves cannot be treated. In the mild form of the disease, treatment is generally not necessary. Severe lesions may cause the birds to stop eating. In these cases, supportive care (tube-feeding and fluids) is indicated. Ulcerated lesions may become infected and antibiotic therapy is indicated in these birds. Vitamin A supplementation also is suggested to be therapeutic. Surgical removal of pox lesions will only cause scarring and should not be attempted.

Prevention and Control

Poxviruses are transmitted by insect bites or by inoculation into abrasions on the skin or mucous membranes. Raising birds indoors or screening the aviary best controls infections in canaries. A canary pox vaccine^d is available. Immunization of pigeons with the pigeon pox vaccine also is an important means of control. Racing pigeons are immunized^e no less than 6 weeks before the racing season begins, as the vaccine is live and will cause the birds to show some signs of illness.

RNA Viruses

PARAMYXOVIRUS 1 (PMV-1) EXOTIC NEWCASTLE DISEASE VIRUS

Applied Biology

Nine serogroups of avian paramyxoviruses are recognized.

Fig 32.9 | The dry form of pox in a chicken.

Within each paramyxovirus serogroup there may be many strains. PMV-1 or the Newcastle disease virus strains are defined immunologically, genetically and by their pathogenicity to chicken embryos or chicks. Velogenic viruses are highly pathogenic to chickens. These viruses can be divided into those that cause predominately hemorrhagic lesions of the digestive tract — viscerotrophic velogenic Newcastle disease virus (VVND) — and those that cause predominately respiratory and central nervous system lesions — neurotropic velogenic Newcastle disease virus (NVND). Less pathogenic forms that primarily cause disease in young chickens are called mesogenic pathotypes, and those that cause little or no disease in the chicken are called lentogenic pathotypes. The virulence of PMV-1 virus for chickens does not consistently reflect the virulence of the virus in other species, as VVND may cause only mild signs in companion birds, and mesogenic

EXOTIC NEWCASTLE DISEASE VIRUS

(END) and pigeon paramyxovirus. 1,24

viruses have caused devastating outbreaks of disease in

wild birds. The two most important PMV-1 viruses that

the practitioner confronts are the highly pathogenic

VVND strain known as exotic Newcastle disease virus

END is a highly virulent virus that has a devastating impact on poultry worldwide. It has been excluded from many nations in the world by strict laws governing the movement of birds. In the USA, all birds entering the country are required to go through a 30-day governmentmonitored quarantine. Random birds and birds that die in quarantine are tested for END. Illegal movements of parrots across the Mexican border have been responsible for limited outbreaks of END in the USA in the past. The 2003 outbreak occurring in California, Nevada, Arizona and Texas is speculated to have resulted from illegal

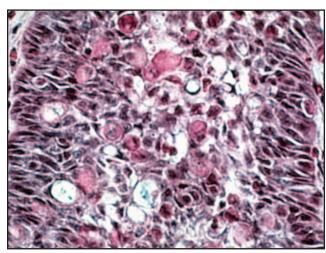

Fig 32.10 | Hematoxylin and eosin-stained section of an avian pox lesion. The round eosinophilic intracytoplasmic inclusions are characteristic of those produced by poxviruses.

movements of fighting cocks from Mexico. Infected chickens shed virus through their respiratory system and feces. Inhalation of the virus may be an important means of transmission when birds are in direct contact. Movement of the virus between flocks results from the movement of infected birds and the movement of the virus on contaminated vehicles and other equipment, clothes and feed sacks. END can colonize the conjunctiva of the human eye where it can persist for at least 48 hours, but it is not known if this plays a role in END dissemination. Vertical transmission of virus is not believed to play an important role in END dissemination.

Clinical Presentation and Diagnosis

END in Poultry

END is as likely to appear in small, privately owned collections of chickens as it is in large poultry operations. Therefore, it is entirely possible that private practitioners will be presented with chickens with this reportable disease.

The first indication of END in a flock of chickens may be the sudden onset of mortality with few antemortem signs. Signs are generally non-specific and may involve the gastrointestinal tract, respiratory system, central nervous system or a combination of these systems. Sneezing, coughing, nasal discharge and dyspnea, swelling around the eyes and the head, green diarrhea, depression, weakness, muscle fasciculations, torticollis, paralysis and sudden death are all listed as signs associated with the 2003 outbreak in the southwestern USA. Birds with these signs should be immediately reported to local regulatory veterinarians. Necropsies of these birds are not performed in the clinic but at official diagnostic facilities.

Gross lesions also can be extremely variable. However, lesions that are highly suggestive of END include hemorrhagic lesions of the conjunctiva, esophagus, proventriculus, small intestines, ceca and cloaca. Tracheal hemorrhage may be a significant lesion in birds infected with certain strains. Birds with CNS signs may not have gross lesions.

END in Parrots

END has entered the USA on several occasions in smuggled parrots. Although the entry was along the USA-Mexico border, often the disease was not recognized until these parrots had made it to northern states. Outbreaks have typically been associated with nestling yellow-naped (Amazona ochrocephala auropalliata) and double yellow-headed Amazon parrots (A. ochrocephala ochrocephala). Signs are not specific and include depression, anorexia, weight loss and diarrhea. Respiratory signs may or may not be present. Ataxia, torticollis, opisthotonus, head bobbing, chorea and paralysis may occur in birds surviving the acute form of the disease. The development of neurologic signs in a sick bird should alert the veterinarian that he or she may be dealing with END. Recovery can occur, and recovered birds may shed virus for months to years. If this disease is suspected, a regulatory veterinarian should be immediately contacted.

Prevention and Protection

The first line of defense against END is controlling the movement of birds into a country. When this fails and the disease infects poultry, the situation is catastrophic. Under these circumstances, efforts are made to isolate the virus to a specific geographic area by stopping the movement of birds. Then a door-to-door campaign is undertaken to identify and slaughter all flocks with the disease. An extensive public education effort is necessary to keep this disease from spreading. In affected areas, breeders of companion birds are significantly impacted. Bird shows and sales are banned, and movement of birds out of the quarantined areas is prohibited.

Veterinarians in the quarantined areas and in areas where the disease has the potential of spreading will be asked by aviculturists what they can do to protect their flocks. The most important means of preventing END is to maintain a closed flock. This means that no birds are introduced to the aviary until the outbreak is under control. If owners are outside of the quarantine area and must bring in new birds, these birds are isolated in a separate facility for 30 days before being introduced into a flock. A veterinarian should examine all birds showing any sign of disease. A closed colony also means restricted access to the public. In quarantine areas, visitors who own birds or might have been around birds should be completely barred from the facility. Footbaths should be placed at the entranceway to the aviary, and every effort should be made to make sure that anything brought

onto the premises, including food, has not been exposed to other birds.

There is no desire on the part of regulatory veterinarians to unnecessarily kill companion birds. Therefore, in the USA, consideration is given to the specific circumstances of the home or the aviary before action is taken. For maximum protection, birds are housed indoors. If this is not possible, they should be housed in a way that keeps out all wild birds and rodents. A fence preventing loose neighborhood birds from entering the facility is critical. It is highly recommended that all exotic bird owners not keep poultry, or if they do, that the poultry be confined to a cage and isolated the same way the companion birds are isolated. Food and water dishes are covered so the droppings of wild birds cannot contaminate them. An effective biosecurity protocol as described is critical. If END is found in close proximity to an aviary, the aviary is likely to be quarantined. Owners will then be required to follow specific quarantine measures, including having their birds swabbed twice at a 15-day interval. If END is found in a flock, the birds will be euthanized. For more detailed information see the California Animal Health and Food Safety Services Web site at www.cdfa.ca.gov. Immunization of companion birds with Newcastle disease vaccines intended for poultry is not recommended. It also should be noted that immunized poultry still may contract END, and their vaccination status will not impact the outcome of the flock if they are exposed.

PMV-1 IN PIGEONS (PPMV-1)

Applied Biology

Pigeon paramyxovirus-1 (PPMV-1) was first recognized in the early 1980s and has since disseminated throughout the world. It is found in feral pigeon populations and is a significant problem in racing pigeon flocks. Evolution of this virus has resulted in changes in its virulence and clinical manifestations. PPMV-1 is not restricted to pigeons and has been identified in feral Eurasian collared doves (*Streptopelia decaocto*). ⁴⁵ The strain of virus identified in these doves, however, appears to be adapted to them and varies somewhat from that found in pigeons. ^{8,24,45}

Clinical Presentation and Diagnosis

PPMV-1 may present in two ways. In the first, neurologic signs predominate. Ataxia and torticollis are the most common signs. The second presentation is polyuria with or without neurologic signs. In both forms of the disease, many birds in a loft will show signs and mortality can be high. Affected birds should be submitted for necropsy to verify the infection.

Prevention

PPMV-1 is disseminated by contact with other pigeons. It is particularly common for it to be introduced to a loft when pigeons are raced, as the birds are in close contact with birds from other flocks prior to the race. Immunization with a PPMV-1 vaccine^f at least 6 weeks prior to the racing season is recommended on a yearly basis.

OTHER PARAMYXOVIRUSES

Paramyxovirus 2 (PMV-2)

PMV-2 rarely causes disease in companion birds. It has been associated with contact with wild passerine birds, particularly finches, and should be considered a differential for birds that are showing respiratory signs.

Paramyxovirus 3 (PMV-3)

PMV-3 has been recognized in multiple nations around the world, but its basic biology is poorly understood. It appears to cause subclinical infections in some birds and it is these birds that are responsible for the spread of infection. Disease is reported most frequently in Neophema species, lovebirds, cockatiels and Amazon parrots, although recently the disease also has been seen in African grey parrots. Signs of infection may be non-specific and precede death by 24 to 48 hours. Birds with a longer duration of signs will develop CNS signs resembling those seen with END. In some cases, respiratory signs also may occur. Chronic infections in Neophema species often result in chronic pancreatitis. These birds have voluminous stools that contain undigested starch and fat. PMV-3 infections also are reported in finches with signs of diarrhea, dysphagia, conjunctivitis and dyspnea. 22,24

Antemortem diagnostic assays have not been consistently effective in identifying birds with disease and asymptomatically infected birds. Traditionally, birds infected with PMVs will produce antibodies that will inhibit virus-induced agglutination of red blood cells. This may be true in some parrots with acute PMV-3, but may not be true in chronic infections. Current efforts to develop an ELISA assay to detect chronically infected birds may help to resolve this issue. Molecular-based technology also may prove to be beneficial in the diagnosis of these infections.

AVIAN INFLUENZA

Avian influenza is a rare disease of companion birds. It is reported to cause non-specific signs as well as signs related to the central nervous system. It is readily recovered from swabs of the cloaca and trachea.

EASTERN EQUINE **ENCEPHALITIS (EEE)**

The importance of EEE in parrots is unclear. EEE was implicated in a disease of 7- to 12-week-old macaws. The birds showed varied signs from sudden death to decreased appetite with abdominal distention. Grossly, serositis with extensive abdominal effusion was noted. Histologically, hepatic disease, interstitial pneumonia and lymphocytic proventriculitis were consistent findings. This disease has been termed polyserositis. It is the author's experience that this disease is extremely rare. However, edema and ascites occur with some degree of frequency following APV infections, and this disease and its associated lesions may be mistaken for polyserositis.

WEST NILE VIRUS (WNV)

Applied Biology

WNV is a flavivirus that is a member of the Japanese encephalitis virus complex. WNV can be divided into two lineages. Lineage 1 has a wide distribution. It has been isolated from Africa, Europe, the Middle East, India, Australia and the USA. Lineage 2 is confined to Africa. Recently, outbreaks of WNV have occurred in France, Romania, Italy, Russia and Israel. The outbreak in Israel was atypical because the virus had an apparent increased virulence for humans and birds. A strain of WNV essentially identical to the strain found in Israel was first identified in New York City in 1999. By the time of this writing, it has spread widely and has been identified in the majority of states in the USA and in several provinces in Canada. It is expected that it will continue to expand its range into Central and South America in the coming years. 15,20

Birds are the primary vertebrate host for WNV. Mosquitoes, particularly the members of the genus *Culex*, are the insect vectors. It has been postulated that hippoboscid flies also may be vectors of WNV, but this has not been experimentally tested (M. Taylor, personal communication, 2002). After ingesting blood from a viremic bird, the virus is amplified in the digestive tract and salivary gland of the mosquito. Bird infection occurs when an infected mosquito bites a bird. After a bird is infected, it remains viremic from 4 to 7 days. The magnitude of the viremia depends on the species infected. Crows, magpies, house sparrows (Passer domesticus) and other passerines appear to develop the highest concentrations of virus in the blood and have the longest duration of viremia. WNV may persist in the skin after the cessation of viremia, allowing mosquito infection for an as-yetundetermined period of time after infection.

Preliminary studies suggest that consumption of animals infected with WNV and even ingestion of infected mosquitoes will result in infection in some species of birds. Close contact also can result in viral dissemination between birds. Virus can be found in the oral cavity and cloaca of infected birds for 9 or more days after infection, and it is a reasonable hypothesis to assume that it is present in saliva and droppings. WNV persists in the tissues of some species that survive for as long as 14 days after infection. Experiments have not been done to show if it persists longer than this.¹⁶

Clinical Presentation

WNV can infect and is believed to have caused death in a wide range of species. Birds particularly susceptible to disease caused by WNV include crows, blue jays (*Cyancocitta cristata*), magpies, accipiters, red-tailed hawks (*Buteo jamaicensis*) and several species of northern owls. Ruffed grouse (*Bonasa umbellus*), gulls, house sparrows, robins (*Turdus migratorius*) and mourning doves (*Zenaida macroura*) make a significant number of reported cases, but reported disease in these species is less than 10% of that reported for crows. Naturally and experimentally infected geese appear to be sensitive to disease from WNV. Chickens, turkeys and at least some species of psittacine birds appear to be relatively refractory to disease.

WNV infection has a seasonal distribution in temperate climates. The first cases are seen in the spring and then continue through the summer. A short course of lethargy followed by death may be the only signs seen. Other birds, however, develop signs of central nervous system disease, including ataxia, tremors, weakness, seizures and abnormal head postures prior to death. Anisocoria and impaired vision also were noted in some birds. Observations by practitioners suggest that some birds may show mild signs of illness and then recover. 41

Diagnosis

Necropsy findings suggestive of WNV disease include intraosseous hemorrhage of the calvaria and hemorrhage of the meninges, mucosa and serosa of the gastrointestinal tract. Splenomegaly is minimal to marked. Focal, linear, or diffuse myocardial pallor also may be present. Microscopic lesions of the brain, heart, pancreas, intestines and spleen are highly suggestive of WNV disease. Infection can be confirmed by isolating the virus from oral and cloacal swabs, brain, heart, kidney, liver, lung and spleen or PCR of these tissues.

Neutralizing virus antibody is detected in the majority of birds within 14 days of infection. Plaque reduction assays and hemagglutination inhibition assays are used to detect antibodies to WNV.^{15,16,41}

Prevention

WNV has created panic in the general bird-owning population in the USA and has been of great concern to wildlife and zoo veterinarians. Many zoo veterinarians have elected to use the West Nile virus vaccineg for horses to vaccinate birds. The equine dose is 1 ml. Experimental immunization using a 0.5-ml dose given twice 2 weeks apart did not induce an antibody response in cockatiels. A full 1.0-ml dose given three times, 3 weeks apart, did induce an antibody titer in some but not all birds immunized at the Houston Zoo (J. Flanagan, personal communication, 2003). Adverse reactions to the vaccine were not noted. A hemolytic anemia, however, has been reported in lories immunized 1 year after their first set of immunizations the year before. Similar problems have not been noted at the Houston Zoo in birds that have been immunized 2 years in a row (J. Flanagan, personal communication, 2003). Given that it is not known how protective this vaccine is for birds and that at least one institution has seen adverse effects that may be linked to immunization with it, use of this vaccine should be considered a last resort when other mosquito control options are not available. An immunization schedule that has been used has been to give a 1-ml dose of the vaccine every 3 weeks for three immunizations. The vaccine can be divided and given in multiple sites in smaller birds.

Disease in psittacine birds is rare; therefore, immunization of psittacine birds is not recommended at this time. Concerned pet owners should keep their birds indoors in the warmer months of the year.

REOVIRUS

A reovirus was found to be one of several pathogens causing a complex of diseases in recently imported African grey parrots, but also was seen in several other species including cockatoos. Because imported wild birds are rarely seen in practice today in the USA, this disease has essentially disappeared. Wild-caught African grey parrots are, however, still imported into Europe, and this disease continues to be a problem there.

Clinical Presentation

The signs of disease have varied to some degree with the specific outbreak. Signs in outbreaks seen in the USA included depression, weakness, weight loss, edema of the legs and head, and paralysis. Anemia, leukopenia and elevated liver enzymes also are reported. More recent outbreaks in African grey parrots imported into Italy showed respiratory signs, including coughing, nasal discharge and increased lung sounds. The disease had a prolonged course and affected birds died. Australian king parrots also were affected with this disease, but these birds died suddenly.

Natural reovirus infections are often complicated by concurrent infections with multiple other infectious agents, including bacteria, Aspergillus spp. and other viruses. Each of these pathogens contributes to the clinical picture of disease.

Diagnosis

Diagnosis in the live bird is probably impossible. However, this disease should be suspected in recently imported wild-caught African grey parrots and birds that are in contact with them. Gross lesions include enlargement of the liver and the kidney, with focal depressed discoloration of the capsular and cut surfaces of the liver. Serosal hemorrhages, enteritis and renal enlargement occur less commonly. Lesions from other pathogens also may be present. Histologic lesions are not specific, and virus isolation is necessary to confirm reovirus infection.

Control

There is no means of control for this disease other than to stop importing wild-caught African grey parrots. Isolation of imported African grey parrots from other imported species may prevent some losses.

RETROVIRUSES

Retroviruses are important causes of disease in waterfowl and gallinaceous birds. Documentation of retrovirus diseases in companion birds is lacking.

Diseases Thought to be Caused by Viruses

PSITTACINE PROVENTRICULAR DILATATION DISEASE (PDD)

Applied Biology

PDD is a disease of unknown etiology, but circumstantial evidence suggests that one or more viruses cause it. Numerous clinical reports document the spread of PDD through a collection after the introduction of birds that subsequently develop disease. Inoculation of tissue homogenates derived from a bird with PDD induced a histologically identical disease in experimentally infected birds. Viruses and virus particles have been identified in a number of birds with PDD. Several viruses have been identified in birds with PDD or in flocks where PDD was a problem. These include eastern equine encephalitis, enterovirus, coronavirus, reovirus, avian paramyxovirus 1 and paramyxovirus 3.9,10,12 The potential role of paramyxoviruses as the cause of PDD has been strengthened by the development of lesions identical to those seen in PDD in a flock of Neophema spp.. They were

experiencing an outbreak of PMV-3 infection: these findings were strengthened by the discovery of antibodies to PMV-1 in birds with PDD, and isolation of a low virulent strain of PMV-1 from the spinal cord of 6 of 32 parrots with PDD. 11,12,22 It is hoped that the slow but steady progress made by investigators working with this disease will soon lead to the discovery of its etiologic agent.

Clinical manifestations of the disease are the result of a lymphoplasmacytic inflammation of the nerves of the gastrointestinal tract and brain, spinal cord and peripheral nerves.5 Lesions also may be found in the heart and adrenal gland. Lesions are rarely diffuse and are variable in their severity. As a result, clinical signs of disease vary from case to case.

Clinical Presentation and Diagnosis

PDD occurs most frequently in African grey parrots, macaws, Amazon parrots, cockatoos and conures, but it is possible that all parrot species are susceptible.²⁴ It also may occur in non-psittacine birds, as a disease with similar lesions has been observed in Canada geese, a redtailed hawk and flamingos. There is no sex predilection for PDD. The median age of onset of PDD is 3 to 4 years, but birds as young as 10 weeks and as old as 17 years have been documented with lesions consistent with PDD. Domestically raised and imported birds are equally susceptible to disease. The incubation period for this disease is not known but may be long, as birds isolated from contact with other birds for up to 2 years still have developed this disease.

The number of birds affected by PDD in a collection, the rapidity with which it spreads through a collection and the clinical signs of disease can vary significantly. Birds with the most common form of the disease present with what the owner considers to be an acute onset of disease. There may be a history of regurgitation, anorexia and the presence of undigested seeds in the droppings. Physical examination, however, reveals an emaciated bird. Often the ventriculus can be palpated in the coelomic cavity caudal to the edge of the sternum. Radiographically, the proventriculus is often massively dilated, filling the left side of the coelomic cavity (Figs 32.11, 32.12). Typically, it develops a "J" shape causing the ventriculus to be displaced to the right and ventrally (Fig 32.13). Ultrasound will demonstrate a widely distended proventriculus and ventriculus. Muscle contractions typically are weak, and there is a failure of the junction between the proventriculus and ventriculus to close. Contrast studies show distention of the proventriculus and ventriculus and often the proximal duodenum. Transit time of the contrast material is markedly reduced. Various permutations of this disease may occur, and dilation of the crop, ventriculus, proventriculus or

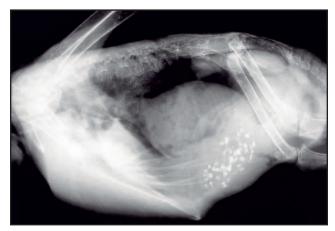

Fig 32.11 | Lateral radiograph of an eclectus parrot reveals proventricular dilatation disease (PDD). Note the massively distended proventriculus.

duodenum may be seen alone or in combination.

CNS signs may be absent, occur in combination with the gastrointestinal signs, or be the only presenting signs. CNS signs may have an acute onset or be very slowly progressive. They may reflect disease of the brain or the spinal cord, and recent evidence suggests that they also may reflect lesions of the lower motor neurons. Ataxia that may be slowly progressive, proprioceptive deficits, paresis and less commonly paralysis, head tremors and rarely seizures have been reported in birds with PDD.

Clinical pathologic findings are not specific but typically reflect the fact that these birds are starving. High uric acid levels were seen in one of the author's cases, because the bird's neurologic disease prevented it from reaching the water bowl and drinking. Overgrowth of the digestive tract with yeast and gram-negative bacteria occurs as the result of gastrointestinal stasis. Initial attempts at diagnosing this disease by serology and electron microscopy of the feces have subsequently been discontinued.

Demonstrating characteristic lesions in a crop biopsy can make a definitive diagnosis of this disease. Not all birds with PDD have crop lesions, so failure to find lesions in a biopsy does not rule out the disease. It is suggested that biopsying the right cranial ventral aspect of the crop, while making sure that it contains a blood vessel, will increase the probability of a lesion being found. Biopsy of the proventriculus is not indicated, as the proventriculus will already be diseased and is likely to dehisce. A partial thickness biopsy of the ventriculus to get a section of the splanchnic nerves is safe but is rarely done.

The progression of PDD through a flock cannot be predicted. Typically, once it is recognized in the flock, additional birds will develop disease in the following months

Fig 32.12 | In this ventral dorsal radiograph of the eclectus parrot in Fig 32.11, the hugely distended proventriculus fills the left lateral coelomic cavity.

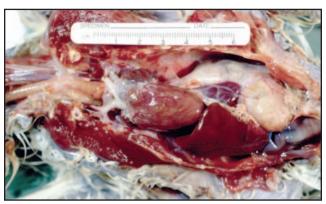

Fig 32.13 | In the gross necropsy of a eclectus with PDD in Figs 32.11 and 32.12, note the massively distended proventriculus that extends laterally beyond the edge of the left liver lobe. The ventriculus is displaced to the right and ventrally.

to years. However, there are times when only an individual bird is affected. Uncommonly, there are outbreaks where multiple birds develop disease within a very short period of time.

As common as this disease is, there are other diseases that can cause nearly identical signs.² Gastrointestinal signs identical to those seen in PDD can be caused by neoplasia of the intestines, intestinal foreign bodies and even massive worm burdens that cause intestinal obstruction. Emptying of the proventriculus and ventriculus appears to be inhibited as long as the intestinal tract is distended. As a result, proventricular dilatation occurs in cases of lower bowel obstruction. Inflammatory disease and neoplastic diseases of the ventriculus and proventriculus also can cause gastrointestinal stasis. Another common cause of gastrointestinal stasis is heavy metal poisoning. Heavy metal poisoning is commonly associated with central nervous system signs as well. A chronic wasting disease caused by internal papillomatosis also resembles PDD.

PDD should be considered as a differential in any bird

with CNS disease. Traumatic injuries, heavy metal poisoning, neoplasia, viral, bacterial and fungal infections of the CNS, nutritional deficiencies and hydrocephalus are additional diseases that can cause similar signs.

Treatment

Celecoxibh, a COX-2 inhibitor, has been advocated as a treatment for PDD.7 Controlled trials with this drug for the treatment of PDD have not been done, but careful clinical reporting suggests that celecoxib does cause regression of the signs of PDD, and birds that otherwise would have died are still alive up to 2 years after treatment. Successful treatment appears to be more likely if PDD is diagnosed before the bird is extremely debilitated. The recommended treatment protocol is to make a suspension of celecoxib in lactulose and to administer 10 mg/kg orally once a day for a minimum of 6 weeks or until the signs resolve completely. Although lactulose was the first agent used to suspend this drug, others may work just as affectively. Anecdotal information suggests that other COX-2 inhibitors also may be effective.

Additional supportive care will need to be supplied to these birds in addition to celecoxib treatment. Birds that are dehydrated should be given fluids. Liquid diets sometimes will pass through the digestive system while solid diets will not. Secondary yeast and bacterial infections also should be treated.

Prevention and Control

Until the etiologic agent of this disease is identified and an appropriate test for that agent is developed, preventive measures will depend on conservative management practices. A detailed history of the source of all new birds and long quarantine periods (>6 months) will reduce the risk of introducing this disease. Historical findings suggest that this disease is more likely to spread in indoor collections. Keeping breeding birds outdoors when possible and maximizing hygiene, ventilation and cage separation in indoor aviaries may reduce the risk of PDD transmission.

The diagnosis of PDD in a collection can be a devastating blow to the aviculturalist. Remember, however, that sooner or later most large collections of birds that have been assembled from multiple sources will have a case of PDD. Isolating birds in contact with birds that have had PDD may prevent dissemination. Incubator-hatching eggs and hand-raising these chicks in isolation also may break the infection cycle, although this has not been proven scientifically.

SEASONAL MORTALITY IN GREAT-BILLED PARROTS

A disease of unknown etiology is killing great-billed parrots (Tanygnathus megalorhynchos) in the USA.26 A survey of great-billed parrot owners suggests that this disease has killed approximately 50% of the great-billed parrots housed in the southern USA during the period of 1995 to 2000. The disease occurs predominately in Gulf Coast States from July to October. Other species that have had similar signs of this disease include the mealy Amazon parrot (Amazona farinosa) and lories. The disease occurs typically in outbreaks, with multiple birds developing signs over a period of 1 to 4 weeks. Both hand-fed nestling parrots and adult parrots are susceptible. Birds housed outside are primarily affected, but disease also has occurred in indoor birds.

Clinical signs of this disease are dramatic. Gastrointestinal motility ceases, so birds stop eating. They may have diarrhea or no droppings at all. Even liquid diets do not pass through the digestive tract. Affected birds rapidly become dehydrated. Birds die within 1 to 3 days, despite aggressive therapy. One case did survive after 2 weeks of treatment, during which time the bird lost nearly 50% of its body weight before its digestive tract began to function again. Intussusception of the intestines occurs in a significant number of cases, resulting in bowel strangulation and necrosis. Blood counts and clinical chemistries show a moderate drop in the total white blood cell count, concentration of the blood from dehydration, an imbalance of electrolytes, elevation in muscle enzymes and an elevation in uric acid, indicating severe dehydration or primary kidney disease or a combination of both.

Consistent specific necropsy findings do not occur. Given the seasonality of this disease, an insect-borne virus has been suspected to cause this disease. However, repeated virus isolation attempts have been unsuccessful. Investigators are currently examining the possibility that a clostridium toxin may be causing this disease.

EPIZOOTIC RESPIRATORY NEOPLASIA OF COCKATIELS

Rapidly growing tumors of the air sacs and lungs occur in cockatiels. Multiple birds in a collection may be affected over a period of several years. The most common clinical sign is the sudden onset of severe dyspnea, although observant owners may see the signs develop over the course of several days. By the time the birds are severely dyspneic, restraint for physical examination or radiographs can be life threatening. If the bird can be radiographed, masses will be seen either in the lung or lungs or in an air sac. These are highly invasive tumors and will penetrate through adjacent vertebrae, compressing the spinal cord. When this occurs, birds present with a progressive or sudden onset of paresis or paralysis of the legs. Attempts to treat these tumors have not been reported.²⁴

These tumors are light tan to yellow. A single pulmonary or air sac mass may be present, but multiple masses are more common. Often they are expanding into the thoracic inlet, resulting in compression of the interclavicular air sac and the trachea. Some of these tumors contain a considerable amount of well-differentiated fat tissue; they may outwardly appear as lipomas. The appearance of the nuclei of the neoplastic cells resembles the nuclear changes seen in cells infected with APV. A history of APV disease has been documented in some of these

aviaries, but APV DNA has not been identified in these

Updates in

Anesthesia and Monitoring

THOMAS M. EDLING, DVM, MSpVM

Although avian anesthesia has made significant advances in the past several years, anesthetizing a bird should never become a procedure to be taken lightly. Unlike common anesthetic procedures in mammals, birds are seldom clinically healthy when anesthesia is utilized. In addition, the anatomy and physiology of birds greatly complicates anesthetic risk. Even a procedure that lasts only 5 minutes can easily put a bird into a hypercapnic state that can be fatal. This being said, birds are now commonly being anesthetized for periods exceeding 2 hours with very little morbidity and mortality. These advances are due to the use of inhalation agents, such as isoflurane^b and sevoflurane^c, plus better monitoring techniques. The newer monitoring techniques effectively control apnea, hypothermia and hypoventilation, the most commonly experienced problems during anesthesia. As in mammals, there is no formula involving respiratory rate and tidal volume that can be employed to correctly determine the ventilatory status of the patient. The only way to accurately assess ventilation in any animal is through some measure of arterial carbon dioxide. Recent advances in avian anesthesia have shown that capnography (the continuous graphing of the carbon dioxide content of expired air) can be effectively used to monitor anesthesia in birds, and the use of intermittent positive pressure ventilators, electrocardiograms (ECG), pulse oximetry and doppler flow probes have greatly advanced the science of anesthesia in avian species.

Systems Overview

PULMONARY SYSTEM

The avian respiratory system is unique to the animal kingdom. It employs two separate and distinct functional systems for ventilation and gas exchange. The ventilatory components consist of the larynx, trachea, syrinx, intra- and extrapulmonary primary bronchi, secondary bronchi, parabronchi, air sacs, skeletal system and respiratory muscles. The gas exchange system utilizes two types of lungs, the paleopulmonic and neopulmonic. Both of these lung types rely on the parabronchi for gas exchange.

Anatomy

The oronasal cavity is separated from the trachea by the larynx, which opens into the trachea through the slotlike glottis. The larynx extends into the pharynx and attaches directly to the base of the tongue. It consists of four laryngeal cartilages: the cricoids, procricoid, and paired arytenoid cartilages.19 This is different from the mammalian larynx in that the thyroid and epiglottic cartilages are absent in birds. The functions of the larynx are to open the glottis during inspiration, aid in swallowing, modulate sound and act as a barrier to keep inappropriate matter from entering the trachea.¹⁹ This anatomy makes intubation of most companion avian species easier than mammalian intubation, as the clinician can visualize the glottis and pass the endotracheal tube with relative ease.

The trachea probably exhibits the greatest degree of variability of any of the respiratory system components. The avian trachea consists of four layers: mucous membrane, submucosa, cartilage and adventitia. The cartilaginous layer forms complete rings throughout the length of the trachea.¹⁹ The internal lining of the larynx and trachea is composed of simple and pseudostratified, ciliated columnar epithelium, with simple alveolar mucous glands and goblet cells.19

Unusual tracheal variations seen in some avian species include modifications such as an inflatable sac-like diverticulum in emus and ruddy ducks, tracheal bulbous expansions in many male Anseriformes, and the complex tracheal loops and coils located in the caudal neck, keel, thorax or a combination. Another unusual tracheal modification is the trachea is divided by a septum in the cranial portion into two tubes in some penguins, mallards and petrels.¹⁹ Most birds commonly seen in a companion avian practice do not have significant tracheal variations.

The avian tracheal modifications create significant func-

tional consequences relating to anesthesia. The most important is tracheal dead air space. The "typical" bird trachea is longer and wider than that of comparably sized mammals, which increases the tracheal dead space volume. Birds compensate for this increased dead air space volume with a deeper and slower breathing pattern.

The syrinx is the sound-producing organ in birds, located at the bifurcation of the trachea. The shape, size and location of the syrinx in the coelomic cavity vary greatly depending on species. The location and structure of the syrinx explains why an intubated bird can still produce sound. The tracheal tube does not pass through the syrinx, thus the syrinx remains functional if enough force is applied to the air sacs, as in resuscitation efforts, or if the bird vocalizes due to a light plane of anesthesia.

The avian bronchial system is composed of three structural levels. 12 The primary bronchus comprises two components: the extrapulmonary portion that extends from the syrinx to the lung parenchyma and the intrapulmonary portion, which extends throughout the length of the lung ending at the abdominal air sac. In most birds, the secondary bronchus is divided into four groups: medioventral, mediodorsal, lateroventral and laterodorsal, based on their anatomic location.20

Most companion birds have nine airs sacs comprised of the paired cervical, single clavicular, paired cranial thoracic, paired caudal thoracic and paired abdominal air sacs. Based on their bronchial connections, air sacs are separated functionally into two groups. The cranial group consists of the cervical, clavicular and cranial thoracic air sacs, and the caudal group comprises the caudal thoracic and abdominal air sacs. Functionally, the air sacs serve as bellows to the lung. They provide airflow to the relatively rigid avian lung during both inspiration and expiration; but, the air sacs are poorly vascularized and contribute less than 5% of the total respiratory system gas exchange.17

VENTILATION

In birds, unlike in mammals, both inspiration and expiration require muscular activity. When the inspiratory muscles contract, the internal volume of the coelomic cavity increases. Pressures within the air sacs become negative, relative to ambient atmospheric pressure, and air flows from the atmosphere into the respiratory system, across the gas exchange surfaces of the lungs and into the air sacs.12 The reverse process occurs with contraction of the expiratory muscles: air flows from the air sacs across the gas exchange surface of the lungs and out to the atmosphere. During the resting phase, the system stops halfway between inspiration and expiration.

Gas Exchange

In the avian patient, gas exchange occurs in the parabronchus. The parabronchi are long, narrow tubes that have numerous openings into chambers termed atria. The atria have funnel-shaped ducts (infundibula) that lead to air capillaries.²⁵ The air capillaries form an anastomosing, three-dimensional network interlaced with a similarly structured network of blood capillaries where gas exchange takes place.¹²

There are two types of parabronchial tissues in the avian lung. The paleopulmonic parabronchial tissue, consisting of parallel, minimally anastomosing parabronchi, is found in all birds. The second type, neopulmonic parabronchi tissue, is a network of anastomosing parabronchi located in the caudolateral portion of the lung. Fenguins and emus have only paleopulmonic parabronchi. Pigeons, ducks and cranes have both types of tissues, with the neopulmonic parabronchi accounting for 10 to 12% of the total lung volume in these species. In songbirds and parrots, the neopulmonic parabronchi are more developed and may account for 20 to 25% of the total lung volume.

During inspiration and expiration, the direction of gas flow in the paleopulmonic parabronchi is unidirectional, whereas the direction of gas flow in the neopulmonic parabronchi is bi-directional. A process involving aero-dynamic valving controls the direction of gas flow through the intrapulmonary primary bronchus, secondary bronchi and the paleopulmonic parabronchi.²⁶

The gas exchange system in the avian parabronchi is best described with a crosscurrent model. In this system, parabronchial gas is constantly changing in composition as it flows along the length of the lung. The degree to which capillary blood is oxygenated and carbon dioxide is eliminated depends on where the blood contacts the blood-gas interface. Another important note in this crosscurrent design is that it is not dependent on the direction of gas flow. Gas exchange occurs equally well with gas flow originating from either end of the parabronchus.

The respiratory gas volume per unit body mass of the avian respiratory system is 2 to 4 times that of a dog. Although the volume of gas in the parabronchi and air capillaries is only 10% of the total specific volume in birds, in the mammalian lung it is 96%. This results in a small functional residual capacity (FRC) in birds and makes periods of apnea critical. Without airflow through the lungs, gas exchange does not occur and the physiological acid-base balance maintained by the respiratory system is made ineffective. Apneic episodes will cause

significant problems during anesthesia and must be carefully managed.

Control

The control of ventilation in birds is complex and poorly understood. In both birds and mammals, respiration originates as a rhythmic motor output from the central nervous system. Reflexes, in response to changes in activity and the environment, modulate the basic rhythm. Birds also possess central and arterial chemoreceptors involved in ventilatory control. Central chemoreceptors respond to changes in the partial pressure of arterial carbon dioxide (PaCO₂) and pH, while arterial chemoreceptors are sensitive to changes in the partial pressure of arterial oxygen (PaO₂), PaCO₂ and pH. These arterial receptors account for the ventilatory response to hypoxia in birds and mammals. In addition, birds have a unique group of receptors, termed intrapulmonary chemoreceptors (IPCs), located in the parabronchial mantle. IPCs are acutely sensitive to CO2 and insensitive to hypoxia, and affect the rate and depth of breathing on a breath-tobreath basis.

CARDIOVASCULAR SYSTEM

The avian heart is a four-chambered muscular pump very similar in function and physiology to that of mammals. In contrast, birds have a proportionally larger heart, larger stroke volume, lower heart rate, higher blood pressure and a higher cardiac output than comparably sized mammals.³⁰ Birds also possess both right and left cranial vena cavae, their aorta arches to the right and they have a tricuspid (right AV) valve with a single leaf. Sympathetic and parasympathetic nerves innervate the atria and ventricles.³⁰

The main cardiac sympathetic neurotransmitters are norepinephrine and epinephrine.³⁰ Excitement increases the concentration of these neurotransmitters, especially epinephrine, which has significant implications because inhalant anesthetics, especially halothane, sensitize the myocardium to catecholamine-induced cardiac arrhythmias. Hypoxia, hypercapnia and anesthetics each depress cardiovascular function.

The conduction system of the avian heart consists of the sinoatrial node, the atrioventricular node and its branches, and Purkinje fibers.³⁰ Birds have type 2 Purkinje fibers that completely penetrate the ventricular myocardium. Ventricular activation appears to originate from both the endocardium and epicardium and vice versa, an adaptation thought to facilitate synchronous beating at high heart rates.

Special Considerations

AIR SACS AND POSITIONING

Air sacs in birds, as previously discussed, do not contribute significantly to gas exchange, and therefore do not play a major role in the uptake of inhalation anesthetics, nor do they accumulate or concentrate anesthetic gases.

The position of the patient during anesthesia can alter ventilation. While a bird is in dorsal recumbency, normal ventilation is reduced. This is primarily due to the weight of the abdominal viscera compressing the abdominal and caudal thoracic air sacs, and reducing their effective volume. While in dorsal recumbency, adequate ventilation can be achieved through the use of intermittent positive pressure ventilation (IPPV).

Because of the flow-through design and the crosscurrent gas exchange in the avian respiratory system, it is possible to provide inhalation anesthetics from either the trachea via the glottis or a cannulated air sac. Cannulation also offers an effective means to ventilate an apneic bird or patient with an obstructed trachea.

DIVE RESPONSE

In some birds, especially waterfowl, episodes of apnea and bradycardia can occur during induction of anesthesia due to a physiologic response termed a dive response. It is thought to be a stress response mediated by stimulation of trigeminal receptors in the beak and nares. It can be elicited simply by placing a mask snugly over a bird's beak without anesthetic gas involvement. The dive response usually happens during the initial phase of induction of gas anesthesia with a mask. If the dive response occurs, turn off the anesthetic gas, remove the mask from the bird's head and provide oxygen to the bird's beak via open anesthetic mask until the bird has recovered.

INTERMITTENT POSITIVE PRESSURE VENTILATION

Providing manual IPPV during inhalation anesthesia is a tried-and-true method for maintaining an animal in a normal physiologic state. The next step in the progression of avian anesthesia is the use of mechanical ventilators to provide IPPV. Mechanical devices can provide a much greater consistency in this effort and free the clinician or technician for other critical duties during surgical procedures. There are two types of assisted ventilation machines — volume-limited and pressure-limited. The volume-limited delivers a set tidal volume, regardless of airway pressure, and the pressure-limited delivers a tidal volume until a predetermined airway pressure is

Fig 33.1 | Sevoflurane vaporizer^a mounted to the ADS (anesthesia delivery system) 1000 mechanical ventilator. The ventilator allows mask induction, and then changes to an endotracheal tube with the flip of a switch.

reached. In pressure-limited ventilation, if the airway becomes occluded, the machine will deliver a lower tidal volume for the same airway pressure. Similarly, changes in lower respiratory compliance over time may alter tidal volume at a given pressure. Thus, gradual hypoventilation may result without the operator becoming aware. In contrast, if the endotracheal tube becomes occluded during pressure regulated volume-limited ventilation, the resulting high airway pressure triggers an alarm that will alert the operator. If the system leaks, gradual hypoventilation may develop due to a loss of a portion of each tidal volume.

Use caution when using all ventilators during surgical procedures in the coelomic cavity, where there is a large opening in an air sac. Because volume-limited ventilators deliver only a preset volume of anesthetic gas, it is almost impossible to control ventilation and anesthesia because most of the anesthetic gas leaks from the opening in the air sac. Although difficult, it is possible to control ventilation under the same circumstances with a pressure-limited ventilator because this type of system will continue to supply anesthetic gas until the preset pressure is achieved. There will be continuous flow from the ventilator through the respiratory tract if there is a large rent.

Pressure- and volume-limited ventilation machines are commonly used in veterinary practice, and manufacturers offer mechanical ventilators designed specifically for small or laboratory animals. These machines are excellent choices for avian anesthesia (Fig 33.1).

It has been hypothesized that it is possible to reverse the direction of gas flow within the avian lung during PPV. Because the crosscurrent gas exchange system is not

dependent on the direction of flow, a reversal of gas flow will not adversely affect gas exchange.9

General Considerations

HISTORY

A complete and thorough history, obtained from the bird's owner, is perhaps the most important information one can acquire prior to anesthesia. The history will provide invaluable information concerning husbandry issues and events that will lead you toward specific concerns. Observant owners will recognize changes in their bird's behavior prior to the clinical manifestation of disease. The history should include all parameters concerning husbandry. These include cage size, cage construction, cage grate, substrate, cage location, perches, toys, food/water bowls, other animals in the household, exposure to other birds (boarding, visits, bird club meetings, etc), exposure to toxins, supervision, changes in household, cleaning (agents used, frequency, etc), and vaccination history, to name a few pertinent factors.

PHYSICAL EXAMINATION

After obtaining the history, quietly observe the bird as it perches in its cage. Watch for signs of awareness and attention to its surrounding environment, body position, feather condition, and respiratory rate and depth. After the initial observations, a thorough physical examination should be performed. Remove the bird from its cage and examine it for any abnormalities. Special attention should be given to the nares, oral cavity, choanal slit, glottis, abdomen, cloaca and muscle mass covering the keel. The heart, lungs and air sacs should be auscultated for signs of disease. Observation of the bird's respiratory rate and depth after handling, when the bird is back on its perch, also provides valuable information on the respiratory condition of the patient. If the physical exam, history or other parameters warrant, blood should be collected for evaluation. Refer to Chapter 6, Maximizing Information from the Physical Examination.

ACCLIMATION

Placing a bird into a new or different environment is usually a stressful situation. When a bird is stressed, it generally will attempt to hide any signs of illness. This can make observing the bird for signs of infirmity difficult. If time and physical parameters allow, acclimating the bird prior to anesthesia can help. If the bird does become acclimated to the new environment, signs of disease that were masked while the bird was stressed may become evident, but they can rarely hide respiratory distress.

It also is possible that the patient will not become acclimated to the new surroundings during the period of time allowed. In these cases, the bird's stress level will elevate and its disease state may worsen. The bird may refuse to eat and drink, and will need to be given supportive care. When managing the highly stressed bird, it is best to bring it into the clinic as closely as possible to the time of anesthesia, while still allowing time for a complete physical evaluation. Preliminary testing such as blood work can be done prior to the day anesthesia will be performed.

FASTING

Ensuring that the crop is empty prior to anesthesia is very important due to the hazards associated with regurgitation. There is controversy as to the length of time a bird should be fasted prior to induction. Because of a bird's high metabolic rate and poor hepatic glycogen storage, it has been recommended that fasting be limited to no more than 2 to 3 hours. However, when working with cockatiel-sized and larger birds in good physical condition, removing their food the night before and their water 2 to 3 hours prior to anesthesia does not appear to be harmful. Always palpate the crop before anesthesia. If there are residues, especially liquid, they can be aspirated prior to anesthesia.

RESTRAINT

The use of proper physical restraint is important in the management of avian patients. Improper capture or restraint can result in serious physical trauma such as fractures, lacerations and dislocations. Owners will judge the veterinarian's clinical abilities on how their bird looks after its visit. Birds must be restrained so that the legs and wings are not allowed to flail. In psittacine restraint, the head must be controlled at all times. In species such as macaws with bare cheek patches, restraining the bird by placing your fingers on these cheek patches can cause bruising, which inevitably will cause the owners to lose confidence in your abilities. Each avian species has its own unique defense mechanism that needs to be addressed to ensure proper restraint. The beak of a parrot can cause significant soft tissue injury and its feet can inflict painful scratches. Birds of prey use their talons as their defense mechanism. Their feet must be carefully restrained or serious injury will result. Although most raptors do not bite as a general rule, great horned owls can use their beaks very effectively. Cranes and herons typically use their long, pointed beaks to attack the eyes of their handlers.

The most common method of restraint is a soft, tightlywoven towel appropriately sized to be able to encircle the patient. The bird is carefully grasped through the

Fig 33.2 | Non-rebreathing circuit. The non-rebreathing anesthesia circuits allow for the removal of CO2 with high oxygen flow (100-200 ml/kg/minute). This type of circuit also is capable of almost instantaneous changes in the percentage of anesthetic gas delivered to the patient when the vaporizer settings are adjusted.

Fig 33.3 | Standard small-mammal face masks with latex gloves fitted across the openings, producing tight-fitting induction masks. The hole should be slightly smaller than the neck size of the animal being induced, and the animal's head should fit completely inside the mask. When fitted correctly, it is possible to provide intermittent positive pressure ventilation in some circumstances.

towel, being careful to control the animal while allowing the sternum freedom of movement for respiration. The animal can either be left in the towel or removed from the towel, depending on the skill and comfort level of the clinician or technician restraining the bird. When using a towel for restraint during an examination it is easy for a bird to become hyperthermic, so be careful to monitor the patient for signs of overheating. During a physical exam, a bird of normal weight will start to pant if wrapped in a towel for more than 5 minutes; therefore, obese birds should be examined within 1 to 2 minutes.

Inhalant Anesthetics

BREATHING CIRCUITS AND **GAS FLOW**

Non-rebreathing circuits such as Magill, Ayre's T-piece, Mapleson systems a-f, Jackson-Rees, Norman mask elbow and Bain circuit are typically used during companion bird anesthesia. These systems rely on a relatively high fresh gas flow rate to remove carbon dioxide. They offer advantages over a rebreathing circuit such as an almost immediate response to vaporizer setting changes and a lower resistance to breathing. Oxygen flow in a nonrebreathing circuit should be 2 to 3 times the minute ventilation or 150 to 200 ml/kg per minute²³ (Fig 33.2).

INDUCTION METHODS

Mask induction techniques are used with companion birds in most circumstances. The masks can range from commercially available small animal masks to plastic bottles and syringe cases (Fig 33.3). The size and shape of

the mask is dependent upon the size and shape of the bird's head and beak. The mask should be stable and as small as possible. Eye lubrication should be administered at this time. During induction, the entire head of the bird should be placed inside the mask, being careful not to cause eye and beak damage.

A disposable latex glove can be placed over the mask opening with a central hole cut for insertion of the head. The hole should be roughly the same size as the bird's neck (Fig 33.4). When fashioned properly, the glove will provide a seal around the patient's neck tight enough to allow for positive pressure ventilation. The tight seal also helps reduce the amount of waste gas released into the environment (Fig 33.5). Too tight of a seal may occlude major vessels.

Other methods of induction have been successfully used. Clear plastic bags can be used to completely enclose a cage and induce anesthesia for patients that are difficult to control. Anesthetic chambers also have been used for induction. Both of these techniques can be effective, but have their disadvantages. The anesthetist cannot physically feel how the bird is responding during induction or have the ability to auscultate the animal using these methods. In addition, the bird can injure itself when not being restrained during the excitement phase of anesthesia.

Several induction techniques have been described in the literature,1 including the use of preoxygenation techniques and slowly increasing the concentration of the gas anesthetic agent until the desired effect has been attained. This method does induce anesthesia, but has the disadvantage of taking longer to achieve a loss of

Fig 33.4 | Induction masks can be made from a variety of existing articles such as plastic bottles, syringe cases, pill containers and plastic containers. Only the shape of the animal's head and your imagination limit the variety of induction masks.

Fig 33.5 | Mask induction of a rose-breasted cockatoo. Note that the head is completely enclosed in the mask and the opening of the mask is covered with a latex glove.

consciousness and may increase the excitement level of the patient. The most common method is to simply place the induction mask over the head of the bird with a high oxygen flow rate (1-2 L/minute), adjust the anesthetic vaporizer concentration to a high concentration (depending on the anesthetic agent, 4 to 5% for isoflurane^b, 7-8% for sevoflurane^c, individual setting is necessary) and securely restrain the bird for the few seconds it takes to achieve induction. The vaporizer setting is then reduced to a setting near the minimum anesthetic concentration (MAC). When performed correctly, this method reduces the induction time and stress level on the bird.

INTUBATION

When short (10 minutes or less), non-invasive procedures such as radiography, blood collection, and physical examinations are to be performed, intubation is usually not necessary. If the procedure is to be invasive or longer than 10 minutes, intubation of the patient can be crucial.

Most birds 100 g in body weight and larger can be intubated with minimal difficulty. It is possible to intubate birds as small as 30 g in body weight, but they present a much greater challenge. In these smaller birds, an endotracheal tube can be fashioned using a red rubber catheter of an appropriate diameter (Fig 33.6). Some birds have unique anatomical features, such as the ventral crest in some hornbills and median tracheal septum in some penguins, which can interfere with intubation. In psittacine birds, intubation can be difficult because the glottis is located at the base of the fleshy tongue.

Care must be taken during intubation to ensure that the trachea is not damaged. The endotracheal tube should provide a good seal with the glottis, but should not fit tightly. If the tube is cuffed, the cuff should not be inflated or should be inflated with tremendous care. An over-

inflated cuff can cause damage to the tracheal mucosa because of the complete cartilaginous rings. Tracheal damage may not become apparent for several days following intubation, when the bird presents with dyspnea due to a stricture in the lumen of the trachea.

The most common problem associated with intubation of companion birds is airway obstruction. Small endotracheal tube diameters and cold, dry gases increase the probability of a complete or partial airway obstruction. As the airway becomes occluded, the expiratory phase of ventilation is prolonged.¹² The obstruction can be corrected by extubating the patient and cleaning the endotracheal tube. Positive pressure ventilation, even during spontaneous breathing, can help prevent the formation of endotracheal mucus plugs, even in the smallest patients.

Once the patient is intubated, the endotracheal tube should be securely attached to the lower beak. This will help prevent the endotracheal tube from becoming dislodged while preparing the bird for the procedure and also will help reduce the likelihood of tracheal damage (Fig 33.7). Another important aspect to address at this juncture of the procedure is caring for the patient's eyes. The eyes of most companion birds are prone to physical damage, since they protrude from their heads. A method to help reduce eye damage is to provide a ring of soft material to encircle the eye that is going to be closest to the table. An eye lubricant also should be administered at this time.

ANESTHETIC POTENCY

Anesthetic potency can be expressed in many ways. One method is to assess the MAC of the inhalation anesthetic during surgical anesthesia. The MAC is generally defined as the minimum alveolar concentration of an anesthetic that produces no response in 50% of patients exposed to

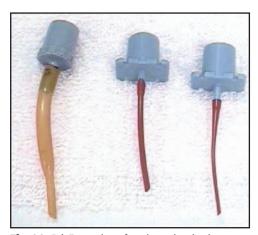

Fig 33.6 | Examples of endotracheal tubes. Cole and red rubber catheter endotracheal tubes can be fashioned for smaller patients.

Fig 33.7 | Intubation of the bird in Fig 33.5 with a modified Cole endotracheal tube. Notice that the endotracheal tube is taped to the lower beak to help avoid damaging the trachea and to allow for a better seal with the glottis.

painful stimulus. MAC values are measured as the endtidal concentration of anesthetic and are not vaporizer settings. In birds, the term MAC is not appropriate because birds do not have an alveolar lung. It has been suggested that in avian species, MAC be defined as the minimum anesthetic concentration required to keep a bird from purposeful movement to a painful stimulus.¹³ The MAC for isoflurane^b in cockatoos, ducks, and Sandhill cranes is 1.44%, 12 1.32% and 1.35%, 9 respectively.

Another method of comparing anesthetic agents is by their ability to cause respiratory depression and apnea in an animal. The Anesthesia Index (AI) can predict this effect: the lower the AI, the greater the chance of apnea. The AI for isoflurane^b in dogs, cats, horses and ducks is 2.51,29 2.40,29 2.3328 and 1.015 respectively. These values indicate that isoflurane^b depresses ventilation more in birds than in mammals.

INHALATION AGENTS

Inhalation anesthetic agents are used to produce general anesthesia. Their safe use requires knowledge of their pharmacologic effects and physical and chemical properties. Anesthetic doses required for surgery produce unconsciousness (hypnosis) and hyporeflexia. With unconsciousness (no response) all pain physiologically still occurs. Inhalation anesthetics provide optimal control of anesthesia, rapid induction and recovery from anesthesia, and relatively few adverse side effects.21

There are two agents currently used for inhalation anesthesia by most avian practitioners, isoflurane^b and sevoflurane^c. A third agent, desflurane, recently has become available, although due to its specialized vaporizer and pungent odor it is doubtful whether it will ever become a commonly used anesthetic agent in avian practice. However, even with the relative high cost of sevoflurane, it quickly is becoming the inhalation anesthetic agent of choice for companion avian practitioners. All three of these inhalation anesthetic agents produce dosedependent central nervous system, respiratory and cardiovascular effects.

Isoflurane^b currently is the preferred choice for avian anesthesia due to its low relative cost, comparatively rapid induction and recovery, low blood solubility and minimal metabolism. In addition, it does not sensitize the heart to catecholamine-induced arrhythmias.²²

Sevoflurane also has been shown to be an excellent anesthetic agent, as it has a lower blood gas partition coefficient than isoflurane^b (sevoflurane^c = 0.69, isoflurane b = 1.41) and is therefore less soluble in blood, although it is less potent (MAC 2-3%). This decreased solubility accounts for the shorter recovery time and time to standing with sevoflurane compared with isoflurane^{b.8} In critical or prolonged surgical procedures, the use of sevoflurane^c can help increase the chance of a successful outcome due to the faster recovery time when compared to other inhalation anesthetics. In addition, sevoflurane does not cause respiratory tract irritation, as do isoflurane^b and desflurane^d, and therefore reduces the stress involved with mask induction.

Desflurane^d is a less potent (MAC 6-8%) anesthetic agent that requires a specialized temperature-controlled and pressurized vaporizer to accurately deliver the anesthetic agent to the patient. It has the lowest blood gas partition coefficient (0.42) of the three agents and tissue solubility (desfluraned and sevoflurane blood-brain tissue coefficient = 1.3 and 1.7, respectively).7 These physical attributes provide for a faster recovery time than those of isoflurane^b and sevoflurane^c, especially after prolonged anesthetic procedures. In humans, the pungency of desfluraned caused respiratory tract irritation, coughing, breath holding and laryngospasms, and thus is not used for mask inductions.⁷

Even when using these reliable anesthetic agents, anesthesia remains risky because it depresses ventilation at concentrations required for surgery. Specifically, as the concentration of isoflurane increases, the PaCO₂ increases, which manifests clinically as a respiratory acidosis.

Halothane is no longer considered to be a safe and reliable anesthetic agent in avian species. As in mammals, halothane sensitizes the heart to catecholamine-induced cardiac dysrhythmias. Fatalities due to pre-existing high levels of circulating catecholamines in stressed birds have been associated with halothane.

Injectable Anesthetics

There are many inherent disadvantages associated with the use of injectable anesthetic agents, the most notable being significant species variation, cardiopulmonary depression, prolonged and violent recoveries, and the difficulty involved in delivering a safe and effective volume.12 The advantages of injectable anesthesia are few and are mostly related to cost and ease of administration. The disadvantages significantly outweigh the advantages in all but the most severe situations, such as field conditions where inhalant anesthesia is not feasible. See Chapter 1, Clinical Practice for a field anesthesia setup. If the decision is made to use injectable anesthesia in companion avian species, the clinician should realize that most of the positive attributes associated with inhalation anesthesia cannot be exploited. When using any of the injectable anesthetic agents, it is advisable to intubate the patients and monitor their physiologic state as if they were undergoing general inhalation anesthesia. Also, an I.V. catheter should be in place for rapid vascular access for fluid therapy and pharmaceuticals

PREANESTHETICS

Parasympatholytic Agents

The use of routine parasympatholytic agents in avian species, as in mammals, is no longer thought to be necessary and is, in fact, counterproductive in most circumstances. Parasympatholytic agents (atropine and glycopyrrolate) in avian species exacerbate thickening of salivary, tracheal and bronchial secretions, and increase the risk for airway obstruction.

Tranquilizers

Tranquilizers such as diazepam and midazolam are benzodiazepines that have excellent muscle relaxant properties. They lack analgesic properties whether used alone or in combination with primary anesthetics such as ketamine. I.V. diazepam can be used to tranquilize a bird prior to mask induction with an inhalant anesthetic, thus reducing the stress involved with the procedure. ¹² Uptake of diazepam is slow and unpredictable with I.M. injection. An important feature of diazepam, in contrast to midazolam, is its shorter duration of action leading to a shorter recovery time. Midazolam is more potent and longer lasting than diazepam, and does not adversely affect mean arterial blood pressure and blood gases in select avian species. I.M. uptake is rapid and almost complete. When midazolam is given to geese, raptors and pigeons, the effects last for several hours after the termination of anesthesia, which can be undesirable. ³¹

Alpha-adrenergic Agents

Xylazine, medetomidine and other related alpha₂-adrenergic agonists have sedative and analgesic properties. They can have profound cardiopulmonary effects including second-degree heart block, bradyarrhythmias and increased sensitivity to catecholamine-induced cardiac arrhythmias. When used alone in high doses, xylazine is associated with respiratory depression, excitement and convulsions in some species. 12 Hypoxemia and hypercapnia were observed in Pekin ducks (Anas domesticus) given xylazine, and a combination of xylazine and ketamine.14 When used in combination with ketamine, the sedative and analgesic effects of xylazine are enhanced. One positive aspect of this class of drug is that an overdose or slow recovery can be treated with an alphaadrenergic antagonist reversal agent such as yohimbine or atipamezole.

Opioids

Opioids are commonly used as a premedication in small mammal medicine, both for presurgical analgesia and to reduce the amount of inhalation anesthesia necessary to achieve a surgical plane. In pigeons, it appears that the kappa opioid receptors account for the majority of the opioid receptor sites. Thus butorphanol, a kappa agonist, may be a better analgesic than mu opioid agonists. In addition, it has been demonstrated that butorphanol reduces the concentration of isoflurane necessary to maintain anesthesia in cockatoos. Please refer to Chapter 8, Pain Management for a comprehensive assessment of analgesia in avian species.

In a recent study it was found that the administration of hydromorphone to healthy dogs undergoing elective ovariohysterectomy or castration may result in transient increases in PaCO₂ postoperatively, and that the administration of hydromorphone or butorphanol may result in transient decreases in PaO₂; however, the increases and decreases were mild and within reference limits.² Due to

the unique physiology of avian species, it is possible that the postoperative increases in $PaCO_2$ and decreases in PaO_2 due to the administration of opioids may be more pronounced. More study in this area is necessary to reach a conclusion.

Local Anesthetics

Local anesthetics are an excellent tool for preemptive analgesia in avian species. However, local anesthetics do not provide any relief from the stress involved with the restraint and handling of the awake bird.

It has been demonstrated in humans and animals that pain is easier to prevent than to treat. In fact, it has been shown that the repeated stimulation of the neurons that mediate nociception in the dorsal horn of the spinal cord can cause them to become hypersensitized. The morphology of these neurons actually changes and becomes "wound up," and as a result, the response to subsequent incoming signals is changed. The neuronal hypersensitivity continues even after the noxious stimulus stops and can last 20 to 100 times longer than the original stimulus.³² The technique of administering a preoperative local anesthetic to block the transmission of noxious stimuli can prevent or attenuate the "windup." This procedure is especially effective for painful procedures such as amputations, fracture repairs and coelomic surgeries. However, when using local anesthetic agents, care must be taken not to induce seizures or cardiac arrest with an overdose. One common method to ensure the correct dosage is to calculate the maximum safe dose and, if necessary, dilute it to a more convenient volume for administration. See Chapter 8, Pain Management for an indepth review of local anesthetic.

In summary, local anesthetic agents should be used primarily as an adjunct to general anesthesia in helping to prevent "windup." In general, they should not be used for local anesthesia in an awake bird due to the high levels of stress involved with handling and restraint, except in rare circumstances where a companion bird is not overly stressed and the procedure is simple such as in the case of a broken toenail.

General Anesthetics

Ketamine hydrochloride, a cyclohexamine, produces a state of catalepsy and can be given by any parenteral route. When used alone, ketamine is suitable for chemical restraint and moderate analgesia for minor surgical and diagnostic procedures, but is not suitable for major surgical procedures. ¹⁴

Ketamine is generally used in conjunction with other drugs such as diazepam or xylazine to improve the quality of the anesthesia by providing more muscle relaxation or increased analgesia. There appears to be significant species variation when using ketamine in birds. For example, in several raptor species and waterfowl, the commercially available form of ketamine induced poorquality chemical restraint and anesthesia.¹⁴

Propofol is a substituted phenol derivative developed for intravenous induction and maintenance of general anesthesia. Its major advantage is that it has a rapid onset and recovery, and thus has very little residual or cumulative effect. Its major disadvantage is its dose-dependent cardiovascular and respiratory depression¹⁶ (see Chapter 8, Pain Management).

Patient Monitoring

Monitoring the avian patient during anesthesia is the most critical aspect of the process. The bird must be maintained and monitored correctly, and appropriate responses to the animal's physiologic state performed in a timely fashion.

Apnea, hypoventilation, hypothermia and regurgitation are the most common problems experienced during anesthesia and, because of the bird's small FRC, periods of apnea are critical. Without adequate airflow through the lungs, gas exchange does not occur and the physiologic acid base balance maintained by the respiratory system is made ineffective.

RESPIRATORY SYSTEM

Both the respiratory rate and tidal volume should be monitored during anesthesia to help assess the adequacy of ventilation. These parameters can be supervised by observing the respiratory rate and pattern and ausculting the coelomic cavity. But, there is no formula involving respiratory rate and tidal volume that can be employed to correctly determine the ventilatory status of the patient. The only way to accurately assess ventilation in an animal is through some measure of arterial CO₂.

One study in African grey parrots (*Psittacus erithacus*) suggests that capnography can be effectively used to monitor arterial CO₂. The study indicates that the End Tidal Carbon Dioxide (ETCO₂) consistently overestimates arterial CO₂ by approximately 5 mmHg.⁴ When using capnography in avian patients, a side stream capnograph should be utilized and the dead air space associated with the endotracheal tube must be minimized. The capnograph can be connected to the breathing circuit through an 18-gauge needle inserted into the lumen of the endotracheal tube adapter (Figs 33.8, 33.9). It is imperative that the needle does not obstruct the luman of the endotracheal tube

Fig 33.8 | Cole endotracheal tube shortened to reduce dead air space. The endotracheal tube adapter has been modified to allow the attachment of a side stream capnograph. This has been accomplished by mounting an 18-ga needle into the lumen of the adapter with the needle bevel facing the patient.

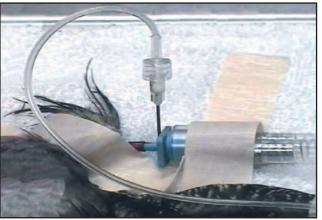

Fig 33.9 | Example of a red rubber catheter with the endotracheal tube adapter modified to allow side stream capnography on a cockatiel.

Positive pressure ventilation through the use of a mechanical ventilator or by manual compression of the reservoir bag can be used to effectively maintain the avian patient during inhalation anesthesia. During positive pressure ventilation, airway pressures should not exceed 15 to 20 cm H₂O to prevent volutrauma to the air sacs. When using positive pressure ventilation, adjust the ventilations per minute mechanically or manually according to the ETCO₂, striving to maintain the patient within normal physiologic ranges. A guideline that can be used with some caution was found in studies with African grey parrots. An ETCO₂ of 30 to 45 mmHg indicated adequate ventilation during inhalation anesthesia in African grey parrots.

CIRCULATORY SYSTEM

The heart can be monitored through a number of noninvasive methods such as pulse, auscultation and an electrocardiogram (ECG). Monitoring the pulsations of blood through a peripheral artery can assess heart function. The Doppler flow probee is an effective means to monitor pulse rate and rhythm. Standard bipolar and augmented limb leads can be used to monitor and record the ECG, which reports the electrical activity of the heart. The ECG must be able to detect and accurately record the high heart rates (up to 500 bpm) associated with avian species. A new technique to obtain ECG readings is through the use of an esophageal probef (Figs 33.10, 33.11). The probe is inserted into the esophagus of the patient and attached to the standard ECG via an adapter (Figs 33.12, 33.13). This technique achieves accurate readings and eliminates the need for attaching leads to the limbs. It is difficult to directly measure arterial blood pressure in psittacine birds due to their small size, the invasiveness of the procedure and the cost of the equipment.

CENTRAL NERVOUS SYSTEM

Eye reflexes, jaw tone, cloacal reflex, pedal reflex and muscle relaxation can be used to assess avian patients during anesthesia. One study described the ideal anesthetic level as when the patient's eyelids were completely closed, pupils mydriatic, the pupillary light reflex was delayed, the nictitating membrane moved slowly over the entire cornea, the muscles were all relaxed and all pain reflexes were absent. 10 Breathing depth and frequency are the best manual assessment tools.

OXYGENATION

Ensuring that an adequate PaO₂ is present in a patient's arterial blood is very important. An intubated bird on 100% oxygen during inhalation anesthesia is usually well oxygenated. Problems such as apnea, ventilation perfusion mismatch and tracheal obstructions can significantly alter the partial pressure of arterial oxygen. The only accurate method for determining a patient's arterial oxygen status is through arterial blood gas analysis. Mucous membrane color can be used to monitor change but is not effective in a critical patient. Studies using pulse oximetry indicate that while it is a valuable tool for assessing mammalian oxygen saturation, it is not consistently accurate on avian patients²⁷ (Fig 33.14). It is very important that the anesthetist be careful not to interpret sufficient oxygenation as being adequately ventilated. Birds can be well oxygenated and at the same time be extremely hypercapnic.6 PaO2 is not a reliable indicator of the ventilatory status of a bird or any other animal.

TEMPERATURE

Studies show that without thermal support anesthetized birds rapidly lose heat. The flow of dry anesthetic gases through the respiratory system, removing feathers for sterile skin preparation, surgical skin preparation liquids,

blunted physiologic responses to the reduction in body temperature, the small body mass in relation to the surface area and many other factors all serve to quickly reduce a bird's body temperature during anesthetic procedures. Hypothermia is the most common problem associated with prolonged anesthesia, as it decreases the requirement of anesthetic, and it also causes cardiac instability and prolongs recovery. Hypothermia also is significant after anesthesia because hypothermic patients must then use critical energy reserves to generate heat by shivering. There are many methods for ensuring that a bird's body temperature does not drop significantly during anesthesia, including a circulating water blanket, heated surgery tables, warm towels, warm IV fluids and warm air blankets. When using warm air blankets, be certain to keep the patients' eyes well lubricated, as these devices tend to dry out the animals' eyes. The most effective method for providing heat during anesthesia appears to be from providing an external heat source.24 Korbel showed that medical oxygen has no moisture content and this caused evaporation from the

Fig 33.11 | Overview of the patient attached to the companion ECG probe connected to the combination ECG and pulse oximetery monitor^f. Notice the adapter box to the right of the monitor (black box). The adapter allows standard ECG leads to connect to the esophageal ECG probe.

mucous membranes, dropping body temperature. If he warmed that oxygen and added moisture, he got negligible body temperature loss during anesthesia. 9,10

Recent research has demonstrated that forced-air warming systemsk more effectively minimize hypothermia in avian patients while undergoing inhalant anesthesia than the traditional thermal devices (eg, circulating water blankets and infrared heat emitters) (Tully, T. unpublished data, 2001).

Temperature can be reliably monitored with a long, flexible thermistor probe inserted into the esophagus to the level of the heart. Cloacal temperature monitoring can be accurate, but is dependent on body position and cloacal activity over time.

Anesthetic Emergencies

Emergency situations arising from anesthesia no longer

Fig 33.14 | Several manufacturers offer combination anesthesia monitoring equipment such as this pulse oximeter and ECG instrument^f.

occur as frequently as in the past. It is now common to perform anesthesia on a psittacine bird for 2 or more hours and have a low incidence of morbidity and mortality. This is primarily due to the advances in the practitioner's ability to monitor and maintain the patient within its normal physiologic parameters. Although emergencies are not common, emergency drugs should be prepared and available prior to anesthesia.

COMMON EMERGENCY TREATMENTS

- Doxapram^g Positive inotrope, direct action on respiratory centers in the medulla, stimulates ventilation.
- **Isotonic Crystalloid** Hypotension: Expand blood volume and increase tissue perfusion.
- **Epinephrine HCI**^h Positive inotrope, initiates heartbeats, increases heart rate and cardiac output.
- Atropineⁱ Parasympatholytic effects, may correct supraventricular bradycardia or a slow ventricular rhythm by stimulating supraventricular pacemakers.

Recovery

Recovering the patient following inhalation anesthesia is usually a rapid process once the anesthetic gas is turned off. Disconnect the bird from the anesthetic circuit and flush the circuit with fresh oxygen. Reconnect the bird

to the circuit and continue the recovery with the patient on 100% oxygen.

Most birds will initially experience muscle fasciculations as they become lighter. If the bird is being auscultated at this time, the heart sounds will become less audible due to the muscle movement.4 Care should be taken not to incorrectly interpret this as a deep plane of anesthesia. This is especially important during surgical procedures. As the bird becomes lighter, more apparent movements such as wing flutter and leg withdrawal will become evident. When the patient starts exhibiting jaw movement, it should be extubated to keep it from severing the endotracheal tube. The bird should be held lightly in a towel in an upright position once extubated. Wrapping the towel too tightly will not only inhibit breathing, but can lead to excessive retention of body heat leading to hyperthermia. The mask used for induction, without the latex glove, should be placed over its head or beak to provide oxygen. The patient should be held in this fashion, being careful not to inhibit the movement of the sternum, until it can hold itself upright. At that point it should be placed in a dark, padded box and the box placed in a heated, oxygenated cage. This will allow the animal to fully recover in a less stressful environment. If a bird has not been fasted correctly prior to surgery, regurgitation can occur during recovery. Most patients will appear fully recovered from anesthesia within 30 minutes to 2 hours.

Surgical Resolution of

Orthopedic Disorders

PETER HELMER, DVM, Dipl ABVP-Avian; PATRICK T. REDIG, DVM, PhD

Orthopedic injuries are common in pet bird practice. Some of the more common causes are falling, an impact with a window or ceiling fan, a crushing incident such as being stepped on, or an encounter with a dog or cat.

Definitive fixation of a fracture is rarely an emergency. Due to the traumatic nature of most of these injuries, first priority must be given to stabilizing the patient. Emergency treatment of shock, hemorrhage and sepsis are covered elsewhere. It is important to assess the patient holistically, including diet, husbandry and concurrent medical conditions, without focusing solely on the obvious injuries.

Prior to examination, obtain a thorough history from the owner. Upon initial examination of the patient, orthopedic problems may manifest as lameness, a wing droop, paresis, a swelling or an open wound. Following initial stabilization of the patient, further investigation of these abnormalities is warranted.

The initial orthopedic exam is generally performed with the bird awake. Prior to handling the bird, visually assess it in its cage:

- Does the bird bear weight equally on each leg?
- Are the wings held symmetrically and in the proper position?
- Does the bird grip a perch?
- Is the overall body posture correct?

Fig 34.1 | Wetting with alcohol or removing feathers over a fracture site often reveals the contusion.

Following the initial visual examination, restrain the animal and systematically assess the skeletal system. The skull is palpated and the feathers covering the head parted to examine the head for hemorrhage or other injuries. In small birds, transillumination of the skull may identify intracranial bleeding. The keel is palpated for evidence of a fracture. Palpation and visualization of the entire length of the vertebral column may reveal deviations or swellings. Wings and legs are examined beginning at the proximal aspect and progressing distally. Long bones are assessed for fractures, deviations and swellings, and joints are assessed for appropriate range of motion. The contralateral appendage may be used as a normal for comparison. Be careful examining extended wings, as iatrogenic fractures may result from the bird trying to flap while improperly restrained.

Suspicion or identification of orthopedic injury requires further examination under anesthesia. Isoflurane or sevoflurane are the agents of choice. While under anesthesia, a more complete evaluation of suspicious areas may be performed, including investigation of masses, minor wound debridement and investigation, wetting or plucking of feathers for closer inspection (Fig 34.1), and radiographs may be made.

Radiographic technique and positioning are covered elsewhere. At a minimum, two orthogonal views are required for evaluation of a particular area. Radiographs of the non-affected contralateral limb are often helpful for comparison, especially as anatomy is quite variable between genera of birds.

Following identification of an orthopedic problem, a treatment plan must be formulated. Fractures should be temporarily immobilized with splints or bandages until the patient is otherwise stable enough to undergo surgery for repair.

One must keep in mind that splints and bandages are

usually meant for temporary fixation only.

The selection of an appropriate technique for definitive repair will depend on several variables, including the size of the patient, the degree of postoperative return to function required, cost, the skill of the surgeon and concurrent medical conditions.

The importance of the first of these conditions, the size of the patient, is often underestimated. Many avian orthopedic techniques were developed for use in raptors weighing approximately 1 kg. While it is true that "tie-in" fixators (TIF) was developed on birds around 1 kg in weight, available hardware is such that it can be readily applied to birds 65-100 grams. These techniques may not be feasible in the 20-g canary. The reduction of load associated with smaller size and higher surgical morbidity and mortality of small patients often contribute to a decision to manage fractures more conservatively in small patients.

The goal of every surgeon should be to return each patient to the pre-injury level of activity; however, this is not always possible. Consideration must be given to the quality of life of a non-releasable wild bird postsurgically. Given the same circumstance, a pet parrot may have an excellent quality of life.

The ideal method of fixation must always be offered and recommended, but lower cost alternatives may have to be considered. A lower cost option may sacrifice post-operative return to function, but in a pet this may be an acceptable compromise. Preoperative communication with owners may be as important as the surgical fixation technique.

Finally, all surgeons do not possess the same skill and experience with avian fracture repair. Referral of orthopedic cases to a more experienced surgeon should be considered.

Principles of Orthopedic Repair

The basic fundamental principles of orthopedic repair are similar to other species. The repair technique should promote a functional union of the fragments, share the load on the bone during healing, allow early return to function and have a low morbidity. The ideal hardware for use in this repair would be versatile, effective, adjustable, lightweight, inexpensive and associated with minimal complications.

Although the principles of repair are the same as in other veterinary patients, some important differences exist:

• Bone cortices are thinner and more brittle, resulting in

less holding power for hardware.

- There is less soft tissue covering the bones. As a result, blood and nerve supplies are commonly injured. Fracture segments tend to be unstable and commonly penetrate the skin, with bacterial contamination a common sequela. These fragments of exposed bone are non-viable and commonly form sequestra if incorporated into the repair.
- Bone grafting is not common, as there is little cancellous bone to harvest.
- Load bearing must be rapidly restored to the legs, as locomotion is bipedal.

The healing patterns of avian bone have been examined. 8,19 In adult birds, the amount of time needed for radiographic and histologic union of unilateral radius and ulna fractures in an experimental setting was 5 weeks with internal fixation and 8 weeks with external coaptation. The majority of the callus tissue during healing is derived from the periosteal surface, and the blood supply to the periosteum from surrounding soft tissues is very important. The intramedullary circulation appears to be of less significance in avian bone healing than in mammals. 19

General Methods of Fracture Fixation

CAGE REST

Very few avian fractures are satisfactorily treated with this method of repair. Fractures of the digits as well as greenstick fractures of young birds may be managed in this way. Cage rest also may be appropriate in the management of fractures of non-weight-bearing bones in very small birds such as canaries and finches. Consider decreasing light levels to decrease activity; however, adequate light must be provided at least twice daily for feeding. Also consider the use of smooth-sided cages without perches (eg, aquarium or plastic carrier) to prevent climbing.

EXTERNAL COAPTATION

The use of splints and bandages for fracture repair in the avian patient is limited. Bandages tend to be bulky and cumbersome. They require prolonged immobilization of joints and usually result in poor alignment of fracture fragments. Though this type of repair may be initially less expensive, return to function is typically prolonged and may not be as complete as with internal fixation. Coaptation may be considered if:

- Full return to function is not required.
- Fractures are pathologic as a result of metabolic bone diseases

- Bones are too soft to hold hardware.
- The patient is too small for internal fixation alternatives.
- The surgical or anesthetic risk is judged to be too great.

Commonly used splints include the "figure-8" wrap, which may or may not include a body wrap, the Altman splint, and Robert-Jones bandages with the incorporation of splinting material. The application of the figure-8 wrap and the Robert-Jones bandage are covered in other texts. A description of the application of the Altman splint is found below in Managing Fractures of the Specific Bones, Tibiotarsus.

The use of titanium IM pins may have advantages in comparison to the traditional stainless steel pin. Titanium has a "memory" and can be bent past 180° and spring back to its normal position (Fig 34.2). The titanium pin is measured against the radiograph of the fractured bone. The pin is inserted into the proximal or distal fragment (Fig 34.3). The pin is bent and inserted into the opposite fragment, thus avoiding the need to transgress a joint (Fig 34.4) (G. Harrison, personal communication, 2003). If a larger pin than shown in Fig 34.4 is needed for larger birds, a single titanium IM pin is not used, as the force to bend the larger pin will shatter the bone. Multiple smaller diameter pins are placed in stacking fashion to facilitate bending.

Orthodonture rubber-band impactions also have been used successfully on the tibiotarsus (Fig 34.5) (G. Harrison, personal communication, 2003) (see Chapter 14, Evaluating and Treating the Gastrointestinal System).

HYBRID FIXATORS

The use of both intramedullary (IM) pins and external skeletal fixators (ESF) has been well described for the management of avian fractures. More recently, the use of hybrid fixators, or "tie-in" fixators (TIF), has become more popular. This technique combines an IM pin linked to an ESF (Fig 34.6). Advantages include the relative ease of application, use of a smaller diameter IM pin than would otherwise be used, which causes less damage to the intramedullary blood supply, an increase in resistance to bending forces compared to either ESF or IM pin alone, a decrease in migration of the IM pin or the crosspins, and the ability to gradually remove hardware over time, a process called dynamization, which gradually increases the load bearing of the bone.

The diameter of the IM pin should fill 50 to 60% of the medullary cavity. Following placement, the pin is bent at 90° where it exits the bone. Two or more threaded crosspins are placed. Threaded pins have been demonstrated to have superior bone-holding strength in avian cortices when compared to non-threaded pins.⁴ In one recent

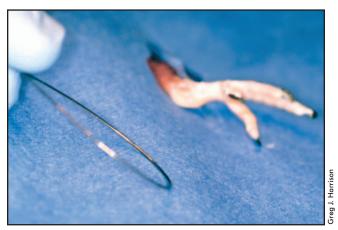

Fig 34.2 | Titanium pin bent past 180°.

A topical bandage covering helps prevent the rubber band from being removed inadvertently.

study, a significant difference in pull-out strength was not demonstrated when comparing positive profile threaded pins vs. negative profile threaded pins.⁴ However, positive profile pins have a higher locking strength at the pin-bone interface and may be considered advantageous in larger bones. The cross-pins are linked to the IM pin with either a metal or acrylic bar. Several ways have been described for linking the pins including rubber tubing (ie, Penrose drain, IV tubing, PVC tubing) that is filled with methylmethacrylate (ie, hoof repair material^a) or car body filler. Also available is a methylmethacrylate putty^b that is semi-solid. This material is kneaded and applied without the need for any tubing. The fumes emitted from this product are significantly less than the hoof repair material.

Managing Fractures of Specific Bones

THORACIC LIMB

Fractures of the scapula, coracoid and clavicle are managed conservatively in all sizes of birds. Figure-8 bandages with body wraps are left in place for approximately 3 weeks, then radiographs are made for reevaluation. Previous recommendations for internal fixation of coracoid fractures, compared to bandaging, resulted in lower success rates in birds of prey, even when severe displacement of fragments existed.¹⁶

Luxations of the elements of the shoulder girdle also are managed conservatively, with the exception of subluxation of the proximal end of the coracoid from the cranial aspect of the sternum. Open reduction of these subluxations is performed via a standard approach to the coracoid. The musculature of the keel is detached and reflected laterally to expose the proximal coracoid. An elevator or osteotome is used for reduction. Transarticular cerclage wire or pins may be placed if instability persists. The wing is bandaged for 3 weeks postoperatively with physical therapy beginning about 10 days postoperatively.

Patagium

The patagium is a soft tissue structure comprising muscular, elastic and tendinous tissues that extends from the shoulder to the metacarpus. This structure forms the leading edge of the wing during flight. Injury to the patagium may result in perforation or tearing. Healing of these injuries often results in contraction of the web, altering the conformation and restricting extension of the wing.

Sutures do not hold well in patagial tissue. This can be overcome by suturing a piece of cardboard slightly larger than the defect over the area. The splint should be replaced every 7 to 10 days until the defect is healed. The support of the cardboard allows extension of the wing during healing.

Humerus

Fractures of the humerus are classified anatomically into one of three zones: (1) The proximal zone, which extends from the tubercles to the pectoral crest, (2) the diaphyseal zone extending from just distal to the pectoral crest to the apex of the distal curvature of the bone, and (3) the distal zone, which is the curved portion of the bone adjacent to the elbow.

Proximal humeral fractures that are minimally displaced often heal well with a figure-8 wrap combined with a wrap to immobilize the wing against the body wall.

However, in order to maximize postoperative flight chances, or in cases of displacement, internal fixation is required. Generally the proximal fragment is too small to drive two cross-pins for external fixation, and there is insufficient purchase for an IM pin. A tension band method of fixation has been described as the most effective technique in the management of these fractures. ¹⁶

The proximal humerus is approached from the dorsal aspect. The major pectoral muscle and the deltoid muscle are elevated from their attachments to the pectoral crest. Two small-diameter pins are driven to exit at the dorsal and ventral aspects of the pectoral crest. Following fracture reduction, the pins are driven into the distal fragment, which results in tension exerted against the medullary cavity. This advancement can be difficult, as the pins bend against the bone and each other. The pins should be driven in an alternating fashion, advancing each only a small amount at a time. The wires are left projecting from the head of the humerus for future removal. This fixation, in addition to wrapping the wing to the body for approximately 1 week, is sufficient in birds under 300 g.

In larger birds, following placement of the cross-pins, a hole is drilled approximately 1 cm distal to the fracture site and another just caudal to the exit point of the wires. A wire is passed through these holes and tightened in a figure-8 pattern to complete the tension band.

Fractures of the humeral diaphysis tend to be oblique and are best managed with a TIF device. The radial nerve, which must be identified and preserved, crosses the dorsal aspect of the humerus at approximately one half of its length.

There are two methods of placing the IM pin in the humerus: 1) the retrograde (ie, away from the fracture site) method that is generally used for fixation of open fractures, and 2) the normograde (ie, toward the fracture site) method for closed fractures.

For retrograde IM pin insertion, the patient is placed in ventral recumbency and the humerus is approached from the dorsal aspect. The diameter of the IM pin should be slightly larger than 50% of the diameter of the marrow cavity. The pin is introduced at the fracture site and driven retrograde, exiting the proximal humerus just distal to the shoulder. The bone chuck is then attached to the free end of the pin and the pin withdrawn until the interval end is flush with the fracture site. The fracture is reduced and the pin driven into the distal fragment. Care must be taken not to penetrate the distal end of the humerus, as damage to the triceps tendon and joint damage are common sequelae.

Fig 34.7 | Dorsal view of the correct introduction site for normograde placement of an IM pin in the humerus. Skin has been removed for illustration purposes.

Normograde pin insertion is often possible in closed diaphyseal fractures (Fig 34.7). A small skin incision is made on the dorsal aspect of the distal humerus just proximal to the lateral (or dorsal) humeral condyle. Following caudal retraction of the triceps tendon, a non-threaded pin is introduced. The fracture is reduced and the pin is driven proximally to engage the cortex of the proximal humerus in the midsection of the pectoral crest.

Regardless of the manner of IM pin insertion, positive profile interface K-wires are placed at the proximal and distal aspects of the humerus to link externally to the IM pin (Fig 34.8). The distal pin is placed first. A small skin incision is made just proximal to the highest point of the lateral (or dorsal) condyle and aimed toward the ventral condyle. The pin is driven until a full thread extends through the opposite cortex. Prior to placing the proximal pin, the wing is folded against the body to properly align the rotation of the fragments. The midsection of the free edge of the pectoral crest is palpated and fingers walked along it until the high point is reached. The pin is driven, parallel to the distal one, until both cortices are engaged. The free end of the IM pin is bent at 90° approximately 2 cm from the skin. The three pins are attached as previously described. It is not recommended to place the distal ESF pin directly through the condyles in fractures of either the distal humerus or the distal tibiotarsus. In many species the intercondylar sulcus is sufficiently deep that the pin will skewer the tendon (triceps or gastrocneumius) that rides in that sulcus. The pin is placed in a slightly proximal position: at the humeral epicondyle to which the tendon of the common digital extensor and supinator muscle arise and in the tibiotarsus, proximal to the supratendinal ridge.

Fractures of the distal humerus (ie, those that occur within 2 to 3 bone diameters of the distal humeral condyles) are problematic, as there is insufficient space for an IM pin to gain purchase in the distal fragment.

Fig 34.8 | Dorsal view of the correct sites for placement of cross-pins in the humerus. Skin has been removed for illustration purposes.

A cross-pinning technique for these supracondylar fractures has been described.16

A skin incision is made dorsally to approach the fracture. The distal fragment is isolated and elevated while protecting the soft tissues and avoiding the separation of comminuted fragments from their soft tissue attachments. Two K-wires are placed in retrograde manner, at an angle such that they exit the fragment on the opposite side of the marrow cavity. When pin ends are flush with the fracture line, the fracture is reduced and the pins are driven into the proximal fragment. Movement is alternated between the pins, advancing about 0.5 cm at a time until properly seated. Pins are placed in the proximal and distal humerus as previously described and the elements attached to form a hybrid fixator device.

Radius and Ulna

The method of repair of fractures of the radius and ulna will depend upon the integrity of the other bone of the pair. External coaptation is a viable option in small companion birds when either the radius or the ulna is fractured and the displacement of fragments is minimal. Potential complications include patagial contraction as a result of prolonged immobilization and the formation of synostosis between any displaced fragments and the other bone. This significantly affects the bird's ability to fly, as both lift and descent require the radius to rotate about the ulna.

Internal fixation of the radius and/or ulna may be accomplished with ESF, IM pins, or a combination forming a TIF. The prognosis for diaphyseal fractures is good; however, some very proximal radius and ulna fractures may be managed only by transarticular ESF, with a very poor prognosis for return to flight. Repair of avulsion fractures of the olecranon has not been reported.

In cases of fracture of both the radius and ulna, fixation

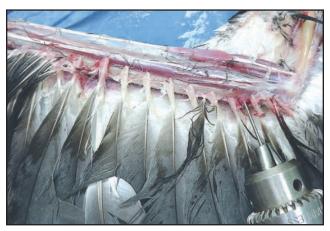

Fig 34.9 | Dorsal view of the correct introduction site for normograde placement of an IM pin in the ulna. Skin removed for illustration purposes.

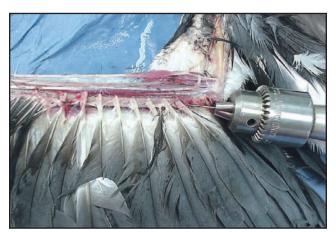

Fig 34.11 | Dorsal view of the normograde placement of an IM pin in the ulna: final alignment. Skin removed for illustration purposes.

of the radius is mandatory, while repair of the ulna is somewhat optional. Given the greater rigidity obtained and the shorter healing time, ulnar fixation is generally recommended. A combination of IM pin fixation of the radius and TIF fixation of the ulna is effective.

IM pins may be placed in the radius and the ulna, however, the method and location of placement is very different. In the radius, the pin is introduced at the site of the fracture and driven retrograde to exit at the distal end of the bone as the carpus is held in flexion. The pin will exit cranial to the carpal joint as the distal radius curves caudally. The fracture is reduced and the pin driven into the proximal fragment. Blunting the proximal tip of the pin may aid in avoiding penetration into the elbow joint.

The ulna is pinned in normograde fashion. Retrograde placement is contraindicated, as it risks exiting the pin at the olecranon and damaging the joint. The covert and down feathers are plucked from the dorsal and caudal aspects of the wing distal to the olecranon. Secondary flight feathers are left untouched. The pin insertion

Fig 34.10 | Dorsal view of the normograde placement of an IM pin in the ulna: gradually reducing the angle of introduction. Skin removed for illustration purposes.

point is on the caudal aspect of the ulna between the shafts of the second- and third-to-last secondary feathers. A small skin incision is made and the pin introduced at nearly a right angle to the caudal bone cortex. As the pin is slowly driven through the cortex, the angle is gradually reduced to become aligned with the long axis of the ulna (Figs 34.9-34.11). The fragments are manipulated into reduction and the pin is seated in the distal aspect of the bone. The proximal ulnar cross-pin is placed between the proximal end of the ulna and the IM pin. It should not impinge upon the elbow joint. The carpal joint must be avoided when placing the distal cross-pin.

Elbow Luxations

Moderate success has been reported in the surgical repair of caudodorsal luxations of the elbow with the following technique. 16 A skin incision is made over the dorsal surface of the wing, and the distal end of the humerus and the proximal antebrachium are exposed. Exposure of the joint is improved by transecting the tendon of origin of the supinator muscle if it remains intact. The proximal end of the ulna is levered into place by inserting a flat periosteal elevator between the proximal ulna and the dorsal (or lateral) humeral condyle and levering the ulna distally until it aligns with the humeral condyle. Application of traction to the distal ulna may be beneficial. The cut ends of the supinator muscle are resutured and a pseudocollateral ligament is made by suturing the edge of the triceps tendon to the common digital extensor tendon. Following closure, a transarticular ESF is placed for 7 to 10 days.

Carpal and Metacarpal Bones

Factors that complicate the management of these fractures include the paucity of soft tissue structures around these bones to protect them and provide blood supply as well as the high incidence of open comminuted fractures

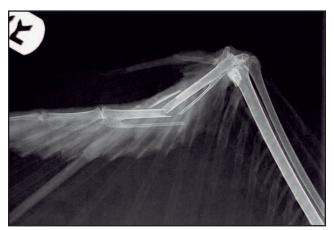

Fig 34.12 | Preoperative view of a fracture of the major and minor metacarpal bones.

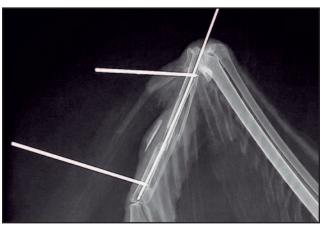

Fig 34.13 | Postoperative view of a reduced fracture of the major and minor metacarpal bones. The IM pin has not yet been bent nor attached to the cross-pins.

as a result of high-energy collisions with wires or projectile impacts. Fractures of the metacarpal bones have a lower rate of successful fixation than other avian fractures.

There are two main techniques used in the management of metacarpal and carpal bone fractures: the curved-edge sandwich splint, and ESF (Type I). The later has yielded the best overall results.

Curved-edge sandwich splints are suitable for stabilizing closed, easily reduced metacarpal fractures. These splints are formed with a right-angle bend in the edge of the splint that runs along the leading edge of the wing. The splint material is cut to a length equal to the distance from the cranial edge of the metacarpus to the distal phalanx and wide enough to cover five to six primary feather bases. The material is laid on the ventral surface of the wing, and the cranial edge is bent at 180° and trimmed flush with the dorsal wing surface. Overlapping adhesive tape strips are applied lengthwise to the dorsal and ventral surfaces of the feather shafts to keep the splint in place. Tape edges are pressed together to provide strength.

ESF are ideal for highly comminuted fractures of the metacarpal bones with extensive soft tissue damage. The fragments can be reduced with minimal soft tissue manipulation.

TIF are not ideal due to the great care that must be taken when placing the IM pin, as there is significant risk of injury to the distal radius. For placement, the pin is introduced at the fracture site and driven proximally while the carpal joint is held in flexion. Following reduction of the fragments, the pin is seated in the distal fragment and bent at 90° to attach to the fixator (Figs 34.12, 34.13). IM pins alone are unsuitable options for metacarpal fracture fixation due to the risk of injury to the radius, coupled with the need for supplemental external coaptation to

control rotation forces.

PELVIC LIMB

The femoral head is connected to the acetabulum by the femoral capital ligament and supported by thickenings of the joint capsule. Traumatic rupture of the femoral capital ligament results in dislocation of the joint.

In small birds, closed reduction and strict cage rest may be effective in the management of coxofemoral luxations; however, in larger species an open reduction is preferred. A cranio-dorsal approach to the joint avoiding the antitrochanter is favored, as exposure is increased. The femoral head is replaced in the acetabulum and soft tissues repaired. Strict cage rest for 3 weeks postoperatively is necessary.

Pins should not be used to fix the femoral head into the acetabulum, as there is a high risk of damaging the kidney and its blood supply on the medial aspect of the pelvis. Additionally, only the rim of the acetabulum is bony in birds; the rest of the structure is fibrous.

Femur

The femur is surrounded by the iliotibialis and femorotibialis medius muscles cranially, the body wall medially, and the flexor cruris and puboischiofemoralis pars medialis muscles caudally. The ischiatic vein, artery and nerve are identified caudolaterally proximally and pass more laterally toward the distal femur. The surgical approach to the femur is made from the lateral aspect.

Fractures of the proximal femur are managed with a tension band apparatus similar to that described for the proximal humerus. The cross-pin technique described for fixation of supracondylar fractures of the humerus is well suited for distal femoral fractures.

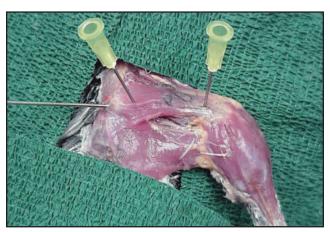

Fig 34.14 | Lateral view of the placement of an IM pin and cross-pins (hypodermia needles) in the femur. Note the neurovascular bundle coursing caudal to the bone. Skin removed for illustration purposes.

Diaphyseal fractures are best managed with a TIF. The IM pin is introduced at the fracture site and retrograded to exit at the hip. Following fracture reduction, the pin is driven into the distal fragment. The cross-pins are placed from slightly craniolateral to caudomedial to best avoid the neurovascular bundle (Fig 34.14). The proximal pin is placed through the femur just distal to the dorsal acetabular rim. The distal pin is placed through the condyles. IM pins alone are often sufficient in birds under 100 g.

Luxations of the Stifle

Luxations of the stifle or femorotibial joint may be managed using one of several methods. One recently reported method involves the placement of IM pins into the femur and the tibiotarsus at the stifle.³ The free ends of these pins, projecting at the stifle, are bent parallel to each other, and with the leg in normal perching position, the pins are held together with a small amount of acrylic. Transarticular ESF placement, with threaded pins placed in the femur and tibiotarsus and connected with acrylic, has also been described.⁶ Ruptured cruciate and collateral ligaments may be repaired using PTFE (Teflon) suture material as a replacement. Hypodermic needles are used to drill holes in the bone and the suture material is then threaded through the needles.

Tibiotarsus

Tibiotarsal fractures are very common in pet birds and in falconry birds. Psittacines tend to have mid- to distal diaphyseal fractures, whereas proximal-third fractures are more common in the raptors used in falconry. Tibiotarsal fractures are usually closed and the prognosis for repair is good. Damage to the tibial and or fibular nerves is not uncommon and must be evaluated. Also, particularly in raptors, bumblefoot of the opposing limb is a concern.

Patients under 300 g will heal very well with a combina-

tion of an IM pin or K-wire and external coaptation in the form of an Altman splint. Hypodermic needles make excellent IM pins, and a 22-gauge needle works very well in budgerigars, cockatiels and similar-sized birds. The pin is introduced into the cranial aspect of the proximal tibiotarsus, avoiding the patellar ligament, and following fracture reduction, advanced into the distal fragment. This is easily accomplished without a chuck, using the plastic hub of the needle to grasp. The hub is then trimmed off the needle. This IM pin technique is combined with an Altman splint to control rotation forces.

To place an Altman splint (Figs 34.15a-d), the bird is placed in lateral recumbency. Overlapping strips of adhesive tape are placed laterally and medially in a horizontal fashion, with the sticky side toward the limb, beginning just proximal to the stifle and continuing distally to immobilize the hock. The sticky sides of the tape are pressed together with hemostats on the cranial and caudal aspects of the limb. The limb should be splinted in a normal perching position. Several layers may be necessary to give strength to the splint, or the tape may be coated with a small amount of cyanoacrylic glue to strengthen it. As an alternative to white adhesive tape that can be difficult to remove, self-adhering bandage material^c can be used in much the same way. Healing takes approximately 3 weeks.

In larger birds, a TIF is the fixation method of choice (Figs 34.16, 34.17). The IM pin may be placed in a normograde fashion as previously described or in retrograde fashion from the fracture site. Pins should not exit into the intertarsal joint, as the tendons of the digital flexor muscles pass through the tibial cartilage in this area and may be damaged.

In planning a surgical approach or placement of the cross-pins, the fibula and neurovascular bundle laterally, and the gastrocnemius muscle caudally, dictate a craniomedial approach. The distal cross-pin is placed from lateral to medial through the condyles. The proximal cross-pin should be introduced on the craniolateral aspect just distal to the tibial plateau and cranial to the fibula. The pin is directed caudomedially. These pins are attached to the IM pin to form the fixator. Type II ESF fixators also have been used with great success in the management of tibiotarsal fractures.

Rotational or angular deformities may be corrected with an osteotomy and either ESF or a TIF.⁶

Tarsometatarsus

The shape of the tarsometatarsus varies among families of birds. The tarsometatarsus of hawks has a flat, C-shaped cross-section with little medullary cavity, whereas in parrots, the bone is rounder with a larger cavity. IM

Figs 34.15a-d | Step-by-step application of an Altman splint.

Fig 34.16 | Preoperative view of the fracture of the tibiotarsus and fibula.

Fig 34.17 | Postoperative view of a reduced fracture of the tibiotarsus and fibula. The IM pin has not yet been attached to the cross-pins.

pins are not recommended, as the flexor tendons that run on the caudal aspect of the bone are affected. ESF cross-pins must be placed with caution to avoid the metatarsal artery and extensor tendons running dorsally, and the flexor tendons ventrally. Splinting of tarsometatarsal fractures with an L-shaped metal splint works well. The toes should be allowed to function freely during recovery to avoid immobilization of the flexor tendons during callus formation.

Phalanges

Closed phalangeal fractures are left unsupported and treated with cage rest. The flexor tendons and their sheaths provide good support. Splinting results in the formation of adhesions and a stiff toe. Compound fractures commonly result in osteomyelitis, and amputation should be considered. Dislocations of phalangeal joints may be reduced under anesthesia without the need for external support. Damaged collateral ligaments may be repaired with 3-0 or 4-0 polyglactin suture.

POSTOPERATIVE CARE

Gauze sponges are applied between the connecting bar and the skin to provide mild compression and to absorb fluids exuding around the pins. These should be changed daily. Pain is managed with opioids or NSAIDs. Analgesia is discussed in Chapter 8, Pain Management and elsewhere in this book. Perioperative antibiotic therapy with bactericidal antibiotics such as cefotaxime^d, enrofloxacin^e, or clavulanated amoxicillin^f is warranted. In patients where osteomyelitis is a concern, clindamycin^h is indicated. The use of antibiotic-impregnated polymethylmethacrylate (AIP-MMA) beads (also called MMP beads) should be considered in patients with open, contaminated fractures with infected bone.

Postoperative radiographs are always indicated to assess the alignment and apposition of the reduction, regardless of the fixation technique used. Radiographs should be repeated in 10 to 14 days to assess healing. Fractures will often heal with significant fibrous callus that will not be initially evident radiographically. Palpation of the fracture site yields additional information regarding fracture stability.

Complications

AMPUTATION

The ability of an individual bird to deal with either thoracic or pelvic limb amputation depends on the bird's size, demeanor and required return to function. Amputation through bone is preferred to disarticulation. The bone end will atrophy and maintain adequate soft tissue coverage.¹⁸

Wing amputations are quite feasible in most parrots, though balance is significantly affected. Most birds will learn to adapt. The wing is generally amputated at the junction of the proximal and middle thirds of the humerus, leaving sufficient soft tissue for closure.

Pelvic limb amputation always carries with it the concern of development of bumblefoot on the opposing limb. Parrots, especially the smaller varieties, fed formulated diets and offered appropriate perches, tolerate pelvic limb amputation well. There are two common sites for amputation: the proximal tarsometatarsus and midfemoral. The advantage of a tarsometatarsal amputation is the creation of a weight-bearing stump covered by the thick, scaly skin in the area. Some birds will traumatize this stump, and a midfemoral amputation site is cosmetic as well as leaving adequate soft tissue for closure. Postoperatively, birds often benefit from wider, padded perches until they regain their balance.

MALUNION/NON-UNION

Malunions and non-unions are the results of instability at the fracture site. Management includes ensuring adequate immobilization of the fracture, which may include additional apparatus, additional coaptation or a decrease in the activity level of the bird. If a callus is present, this material may be removed and packed into the defect as a graft. In more long-standing cases, bone grafting may be required. A piece of bone from the carina may be harvested, chopped into small pieces and packed into the defect. This is cortical bone and may become a sequestrum.

OSTEOMYELITIS

As previously mentioned, many avian fractures are open and contaminated. Routine antibiotic therapy is instituted as discussed. Cases of postoperative osteomyelitis are managed with surgical debridement and antibiotic therapy based on culture and sensitivity. Lincomycinⁱ and clindamycin^h are generally the drugs of choice.

Implantation of AIPMMA beads may be beneficial, as high concentrations of antibiotic are reached in their surrounding area. Consider *Aspergillus* sp. and *Mycobacterium* spp. as etiologic agents in unresponsive cases.

SEPTIC ARTHRITIS

Joints may become infected through a direct penetrating wound or via the hematogenous route. Clinical signs include lameness and swelling of the joint. Diagnosis is obtained through radiographs, cytology and culture of the joint fluid. Radiographic signs of septic arthritis include increased radiodensity of the subchondral bone and osteolysis as the disease progresses. Treatment combines daily irrigation of the joint with saline and an antibiotic, in conjunction with oral antibiotics based on culture and sensitivity. Radiographic bone changes are a poor prognostic indicator. Although the infection may be controlled, a decrease in the range of motion of the joint should be anticipated.

BUMBLEFOOT

Bumblefoot, a combination of pressure sores and infection of the plantar aspect of the foot, is a common condition of captive birds of prey and waterfowl and also is seen in psittacines, primarily cockatiels and Amazon parrots. Predisposing factors include obesity, poor diet, inactivity, inappropriate perches and uneven weight bearing, as is often the case in pelvic limb injuries.

Initial lesions are recognized as hyperemia and flattening of the skin of the digital and metatarsal pads, the sites of maximum weight bearing (Type I) (Figs 34.18, 34.19). These lesions progress if untreated and bacterial invasion of the subcutis occurs, resulting in a scab and mild swelling (Type II) (Figs 34.20, 34.21). Some may further progress to form a caseous abscess with marked swelling and pain (Type III) (Fig 34.22). Infection of the tendon sheaths results in an infection and corresponding cellulitis tracking toward the intertarsal joint and the digits, flexor tendon rupture (Type IV) (Fig 34.23), osteoarthritis of the sesamoid bone ventral to digit II, and septic arthritis of the tarsometatarsal-phalangeal joints (Type V) (Fig 34.24).

Treatment and prognosis depend on the degree of disease, but all birds with lesions should have the following changes made:

- Correct dietary deficiencies. In parrots, it is crucial to convert to a formulated diet.
- Alter perching surfaces to allow more even weight bearing. Wrapping wood perches with bandaging material^c or covering perches with artificial turf or other carpeting material will result in a different weight distribution each time the bird perches.
 Cement and sandpaper-covered surfaces must be eliminated.
- Reduce the bird's weight. This will often accompany conversion to a formulated diet from a high-fat seed diet.

Fig 34.18 | Early Type I bumblefoot in a parrotlet (*Forpus* sp.) that selected only oats from a seed/pellet diet.

Fig 34.19 | Advanced Type I bumblefoot in a budgerigar (*Melopsittacus undulatus*) on an all-seed diet.

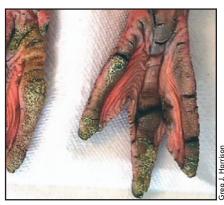

Fig 34.20 | Type II bumblefoot in a flamingo fed an all-grain diet and housed on a poor floor surface.

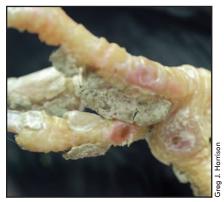

Fig 34.21 | Type II bumblefoot in a mynah bird (*Gracula religiosa*) with iron storage disease.

Fig 34.22 | Advanced Type III bumblefoot in a cockatiel (*Nymphicus hollandicus*) fed an all-seed diet.

Fig 34.23 | Type IV bumblefoot in a 20-year-old cockatiel (Nymphicus hollandicus) with deformed bones, tendons and ligaments fed an all-seed diet.

 Increase exercise. Pets should be encouraged to walk around on various surfaces and must be let out of their cage. Allow flight.

The above changes are usually sufficient for treatment of Type I disease. Refractory cases should be evaluated for other systemic disease that may be decreasing perfusion to the foot or otherwise delaying healing.

All birds with Type II-V bumblefoot should be managed with antibiotics. The choice of drugs is based on culture and sensitivity testing. Good initial choices include the amoxicillin/clavulanic acid^f combinations, enrofloxacin^e, or Lincocin^f.

Type II bumblefoot may be treated with thorough cleaning of the feet and application of medication to soften the scab, such as hydrocolloidal wound dressing material or sodium fusidate ointment. Once the scab is removed, the underlying wound is sutured and bandaged.

More advanced cases (Types III, IV, V) require surgical intervention. Treatment is aimed at wound debridement and re-epithelialization. AIPMMA beads may be left in

Fig 34.24 | Type V bumblefoot in an American bald eagle (*Haliaeetus leucocephalus*) with improper diet and housing.

the wound to increase antibiotic levels locally. Large wounds are managed with a purse-string suture and allowed to granulate in. A rigid foot cast is made to support the foot and raise the plantar surface to avoid contact with the perch.

Prognosis for Types IV and V bumblefoot is guarded to poor. The disease often results in deformity and dysfunction of the toes.

Surgical Resolution of

Soft Tissue Disorders

HEATHER L. BOWLES, DVM, Dipl ABVP-Avian, Certified in Veterinary Acupuncture (Chi Institute); ESPEN ODBERG, DVM; GREG J. HARRISON, DVM, Dipl ABVP-Avian, Dipl ECAMS; JACK J. KOTTWITZ, DVM

Preparation and Considerations for Avian Surgery

PATIENT EVALUATION

A full signalment and history should be obtained and a physical examination performed prior to anesthesia and surgery (see Chapter 6, Maximizing Information from the Physical Examination and Chapter 34, Surgical Resolution of Orthopedic Disorders).

Preoperative diagnostics may include a complete blood count, serum chemistry and electrolyte profile, and other serologic or hematologic tests. The surgeon should evaluate the risk/benefit ratio for each diagnostic test, particularly in smaller avian patients (<100 g). Presurgical blood collection may cause hypovolemia and/or anemia that may dispose these birds to life-threatening intraoperative hemorrhage. Hematologic findings that may preclude or delay elective surgery are similar to those in domestic animals. These include the following:

- 1. An elevated hematocrit, which may indicate dehydration or cardiovascular compromise.
- 2. A decreased hematocrit. Anemic patients have increased surgical risks, particularly if there is perioperative hemorrhage.⁵ Severe anemia (ie, PCV <20%) requires correction or treatment prior to surgery.
- 3. A decreased total protein, which may delay healing as well as indicate underlying metabolic disease.
- 4. Leukocytosis, which may indicate an infectious or inflammatory process, requiring pre-, peri- and postoperative antimicrobial therapy. Perioperative antibiotic or antifungal agents should be administered when indicated.

- 5. Hypocalcemia that may pose an anesthetic risk, compromise cardiac and neurologic function, and impair bone healing subsequent to fracture repair.1 Evaluation of both total calcium and ionized calcium is strongly recommended prior to surgery¹ (M. Stanford, personal communication, 2000), particularly in those patients with associated malnutrition or history of egg production.
- 6. Organ system disease (eg, renal, pancreatic), which may require medical therapy prior to surgery and may influence anesthetic choices.
- 7. Hepatic insufficiency which may debilitate the patient due to decreased hepatic production of clotting factors as well as reduced liver function, that may affect various critical aspects of patient homeostasis.
- 8. Reduced thrombocyte counts, which may predispose the patient to coagulopathy.
- 9. Electrolyte imbalances. 1,5,8

Radiographs and ultrasonography may be utilized in establishing a diagnosis, treatment plan and prognosis, as well as determining the patient's degree of anesthetic and surgical risk.

Cardiovascular function should be thoroughly evaluated prior to anesthesia and surgery. Arrhythmias, murmurs, tachycardia, bradycardia and pulse abnormalities (pulse deficits or jugular pulses) should be investigated with radiographs, electrocardiology, echocardiography and evaluation of blood pressure.5,87

Anorexia, disease and stress may all contribute to nitrogen imbalance. Starvation and disease may result in a hypermetabolic state, and stress may cause an initial hypometabolic state followed by a hypermetabolic state. Hypermetabolism increases the body's protein requirement. Birds have a higher protein requirement than mammals. Protein demands are further increased because there is increased need for tissue repair, blood cell production and antibody production with surgery.^{5,87}

Carbohydrates are a nitrogen-sparing energy source and are recommended for correction of a stress-related negative nitrogen balance. A successful postsurgical patient requires a positive nitrogen balance to facilitate tissue repair, and a source of non-protein energy to meet their increased caloric requirements.⁵ Patients with a decreased blood glucose level should be supported intravenously with dextrose as part of their fluid therapy pre-and intraoperatively.1

Resting basal metabolic rate (BMR) may be determined by using the formula BMR kcal/kg per day = $(K)BW^{.75}$. Additional energy is required for growth, reproduction, disease and tissue repair. Severe trauma and sepsis may increase the patient's energy requirements 1.5 to 3 times their resting requirement. There are several commercially available supplemental diets that can be utilized to meet these nutritional requirements, ranging from juvenile hand-feeding formulas to avian critical care diets5 (see Chapter 7, Emergency and Critical Care).

Malnutrition may lead to obesity, vitamin A deficiency and other nutritionally related diseases. These conditions may pose anesthetic and surgical risks, and predispose the patient to infection, delayed healing and/or coagulopathies.5

PATIENT PREPARATION

Fasting

Birds normally maintain relatively low hepatic glycogen stores. Liver glycogen stores may decrease as much as 90% during a 24 to 36 hour fast and possibly more in small birds. However, it is important for the crop to be completely empty prior to anesthetizing the patient to prevent regurgitation and aspiration. Therefore, general guidelines include a short fast of 2 to 4 hours for birds <300 g body weight, 5 to 8 hours for birds >300 g body weight, 2 to 4 hours for frugivores and 24 to 36 hours for larger raptor species weighing 2 to 4 kg. It is generally recommended to leave water available until 1 hour prior to anesthesia.5

Decreased gastrointestinal motility may alter these recommendations. The crop should be thoroughly palpated immediately prior to anesthesia. If surgery must be performed and the crop is not completely empty, fluid or liquefied food may be aspirated through a feeding tube and/or the head should be elevated during the surgery to prevent regurgitation and aspiration of crop contents. It is advisable to intubate these patients to protect the airway.5 Following intubation, cotton balls or gauze can be placed in the caudal pharynx to prevent reflux of crop contents.

Anesthesia and analgesia are indicated to promote patient comfort and reduce pre-, peri- and postoperative stress (see Chapter 8, Pain Management and Chapter 33, Updates in Anesthesia and Monitoring).

Positioning

Patient positioning varies with the surgical approach. Lateral and dorsal recumbent positions are most common (Fig 35.1). Respiration may be impaired when the avian patient is placed in ventral recumbency. Procedures that may require ventral recumbency include excision of the uropygial gland, surgery of the pygostyle and excision of dorsal feather follicle cysts.1

When the patient has been properly positioned, atraumatic adhesive tape such as masking or certain medical tapes may be used to secure the patient. Restraint

Fig 35.1 | The lateral and ventrodorsal patient positions are most commonly used for avian surgery. Care should be taken to avoid placing pressure on the thorax with surgical drapes, instruments or the surgeon's hands, as birds require movement of the keel and intercostal muscles to expand the thorax for respiration. Tape that is not traumatic to skin and feathers, such as masking or certain medical tape, may be used to position the patient.

Fig 35.2 | Prior to surgery, all feathers 2 to 3 cm from the surgical site should be removed. Standard aseptic technique applies to avian surgery. Chlorhexidine diacetate (0.05%), povidone iodine (1.0%) or chlorhexidine gluconate (4%) rinsed with alcohol and saline are all effective for presurgical skin disinfection.

boards are commercially available and are preferred by some surgeons. It is helpful to secure the patient to a platform that then may be repositioned as needed to facilitate intraoperative adjustments in surgical access.¹

Birds require movement of the keel and intercostal muscles for respiration, therefore, care should be taken to avoid placing any pressure on the thorax with surgical drapes, instruments or the surgeon's hands.¹

THERMOREGULATION

Hypothermia is a significant concern, particularly in small avian species. Several heating systems exist including circulating water heating pads, electric heat pads, heated forced air systems and overhead heat sources. Some of these may not provide adequate supplemental heat to the patient and others may mechanically interfere with the surgeon and/or anesthetist^{5,67} (see Chapter 33, Updates in Anesthesia and Monitoring).

Creating a Sterile Surgical Field

In preparation for surgery the feathers should be removed in a 2 to 3 cm radius beyond the edges of the surgical site (Fig 35.2). It may not be possible to remove all the feathers from the surgical field due to skin trauma, species-specific skin fragility, location of the surgical site, need to retain flight feathers or patient body size. Removal of the rectrices or remiges, which insert into the periosteum of the associated bones, may increase postoperative pain. These larger feathers may instead be wrapped with sterile non-adherent bandage material. The remaining feathers may be retracted from the surgical field with light adhesive tape such as mask-

ing tape. A small amount of alcohol may be used to lightly wet feathers and smooth them away from the surgical site; however, alcohol should not be used when radiosurgery or electrocautery will be employed.

Alternately, sterile, water-soluble lubricant jelly may be used to smooth the feathers out of the surgical field.

Standard aseptic surgical techniques apply to avian surgical procedures. Skin disinfectant scrub should be used to minimize the risk of bacterial contamination of the surgical site without damaging the skin. Chlorhexidine diacetate (0.05%) and povidone iodine (1%) have been found equally effective for skin preparation, and have no significant effect on wound healing. Chlorhexidine gluconate (4%) is equally effective when rinsed with alcohol or saline. Saline provides the benefit of not predisposing patients to hypothermia and does leave sufficient residual chlorhexidine solution bound to the skin. One study demonstrated that 50% of dogs developed erythema, edema, papules, wheals and weeping of serum from the skin when the skin was prepared with povidone iodine. This may suggest that chlorhexidine solutions are a less irritating class of disinfectants.5

Aseptic preparation of the cloaca is difficult. Maximum disinfection can be achieved by irrigating the cloaca with chlorhexidine gluconate (4%), then infusing antibiotic ointment.⁵

There are several lightweight surgical drapes available. Clear adhesive drapes allow the surgeon and anesthetist to monitor the rate and depth of respiration, and may be more effective in maintaining body temperature.

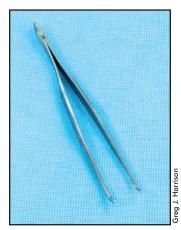

Fig 35.3a | A traditional small-animal thumb forceps with teeth is shown. This instrument has a curved tip and unique jaws for handling delicate tissues.

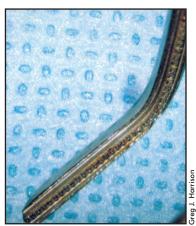

Fig 35.3b | The forceps in Fig 35.3a have unique jaws (40x). The central row of teeth is elevated to fit into a depression on the opposite jaw. The apposing jaw has a recession for the ridge to fit in. On either side of the ridge and recession are alternating teeth and an offset space to receive a tooth. This setup maximizes tissue contact. Dr. Harrison has found this to be the most versatile instrument in avian surgery.

Fig 35.3c | The basic minimal surgical pack should include top-quality instruments with carbide steel inserts. Minimal requirements for a basic surgical pack include Brown-Adson tissue forceps, Adson tissue forceps, smooth-tipped and toothed Bishop-Harmon tissue forceps (used for smaller patients), a larger pair of DeBakey tissue forceps, two or more curved-tip Halstead mosquito hemostats, tenotomy or small Metzenbaum scissors, and two needle holders. The recommended needle holders include a small Mayo-Hegar or Olsen-Hegar needle holder for 3-0 to 5-0 suture, and a smaller Castroviejo or Mathieu-type needle holder for 5-0 to 8-0 suture. The surgical pack also should include small, sterilized gauze pads and cotton swabs.

INSTRUMENTATION

Surgical instruments for avian surgery must be appropriately sized and designed to atraumatically manipulate delicate tissue (Figs 35.3a-c). Microsurgical tools such as those utilized in human vascular surgery, ophthalmic instruments and instruments specifically designed for small veterinary patients may be used. Microsurgical instruments should be of a standard length, counterbalanced and have miniature tips (Fig 35.4a). The length allows for balancing in the hand (Figs 35.4b,c). When utilized correctly, the arm provides stability while the fingers carefully move the tip. This balance, stability, and rounded shape allow for smooth, precise movement, thereby preventing any trauma to delicate tissues, blood vessels or nerves (Fig 35.4a-f). Jeweler's instruments are often used for their small size; however, these are usually not ergonomically designed for microsurgery. Several courses are available for microsurgical training. Microvascular and human plastic surgery techniques are particularly helpful with avian patients.^{1,4,5}

Small, angled (60-90°) mosquito hemostats and hemostatic clip applicators are useful for avian celiotomies (Figs 35.4g-j). These allow increased accessibility to viscera and blood vessels located deep within the coelomic cavity. Angled DeBakey neonatal vascular clamps^a are useful for ovariectomy.24

Sterile gavage and feeding tubes may be used for irrigation, to moisten tissue or to flush hollow viscera.

Tuberculin or other small syringes may be used for suction, as some traditional suction units may traumatize delicate tissues. Mini-Frazier suction tips and Poole-type suction tips may be used in avian patients. The Pooletype suction tip may be fashioned from a rubber feeding tube by creating multiple fenestrations. 1,4,5

Abdominal retractors must adequately retract tissue without causing tissue trauma (Fig 35.5). Mini-Balfour and Alm retractors may be used in larger avian species such as macaws and Amazon parrots. Heiss retractors and ophthalmic eyelid retractors may be used in small avian species such as cockatiels and budgerigars. Lone Star retractors are lightweight and allow the surgeon to achieve retraction at several areas surrounding the surgical site.1,4,5

HEMOSTASIS

Hemostasis is of the utmost importance in birds. Minor hemorrhage can result in severe compromise to these small patients. Large blood vessels are located just below the dermis and care should be taken to either avoid severing or to preempt bleeding prior to transection of these vessels. Several tools exist to assist the surgeon. These include chemical cautery agents, metal clips, radiosurgery, electrocautery and lasers. 1,5 Hemoclips are small, atraumatic, stainless steel clips applied with hemostattype applicators (Fig 35.4i). These applicators facilitate access into small, deep, difficult to reach areas.^{1,5}

Fig 35.4a | Bottom to top: Standard delicate-tissue, small-animal thumb forceps. Regular thumb forceps. Microsurgical thumb forceps.

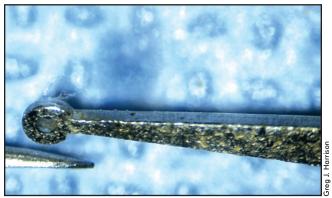

Fig 35.4c | The two tips available for microsurgical forceps (40x). On the left bottom is a fine needle tip that tends to slip if any tissue volume is grasped. On top is a circular or ring tip with titanium dust on the contact surface to aid in grasping. This greatly improves delicate tissue handling and reduces bleeding caused by slipping with the other forceps.

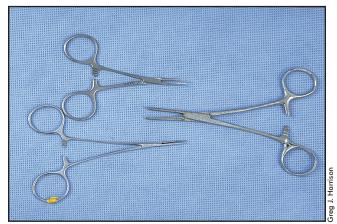

Fig 35.4e | Top to bottom: Delicate-surgery hemostat. Standard hemostat. Microsurgical hemostat.

Fig 35.4b | Microsurgical forceps in Fig 35.4a showing the counterbalance and scooped-out area that fits over the web of the index-thumb finger area of the operator's hand. Grasping the round handles approximates using a writing instrument.

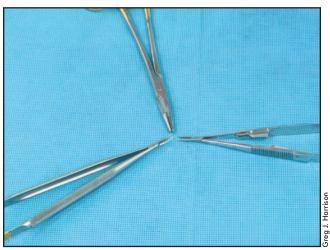

Fig 35.4d | Needle holders. Top: Standard small-animal surgical needle holder. Right: Delicate-tissue needle holder. Left bottom: Microsurgical needle holder. The extra-fine tip and the round handles allow increased speed and accuracy of suturing when handling 6-0 to 10-0 swaged-on suture material.

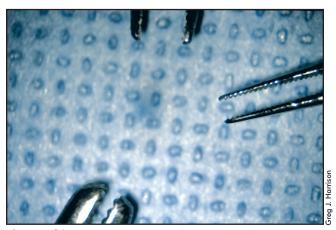

Fig 35.4f | Hemostat tips. Top: Delicate-surgery hemostat. Right: Microsurgical hemostat. Bottom: Standard hemostat. The microsurgical hemostat allows pinpoint grasping. Only the tiny area of concern is grasped. If needed these hemostats can be touched with the radiosurgery tips to coagulate the vessel contained within. Cauterization of surrounding soft tissue should be minimized to prevent unnecessary necrosis.

Fig 35.4g | Various hemoclip applicators. Left to right: Small hemoclip with 20° tip. Small hemoclip with 90° tip. Medium hemoclip with 20° tip. Medium hemoclip with 90° tip. Top: Microsurgical forceps for size comparison.

Fig 35.4h | Loading the hemoclip applicators from a clip cartridge.

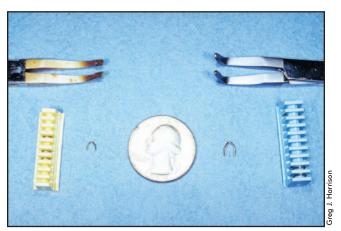

Fig 35.4i | Comparison of a small hemoclip applicator (left), a medium hemoclip applicator (right) and a US 25-cent coin.

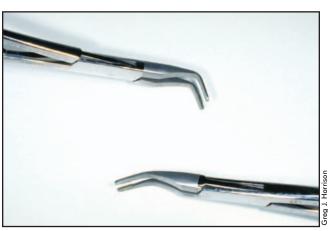

Fig 35.4i | Side view of the hemostat applicator tips. Top: 90° tip. Bottom: 20° tip.

Gel foam, surgical spears, Monsel's solution^c, chemical cautery, collagen sheets, beaded polysaccharide powder^d and direct manual pressure can assist in the control of minor hemorrhage.^{1,5}

WOUND HEALING

Wound healing has been thoroughly evaluated in mammals and determined to occur in a sequential series of events. These include the inflammatory stage, fibroblastic stage, epithelialization phase, contraction phase and the remodeling phase. Cellular and vascular processes of the inflammatory stage have been evaluated in chickens and are similar to that described in mammals. Birds lack significant subcuticular tissue, therefore primary skin closure is often necessary. Excessive scar tissue does not typically form in birds (Fig 35.6).

RADIOSURGERY

Radiosurgery utilizes high-frequency (2-4 MHz) alternat-

ing current to generate energy waves that create vibration and molecular intercellular heat (Fig 35.7a). This results in vaporization of water and rupture of affected cells while the electrode remains cool. The frequency may be manually set to cut tissues or coagulate blood vessels. Coagulation occurs when the current density dehydrates cells and coagulates the cellular contents (Figs 35.7b-e).^{4,5}

When the radiosurgery unit is set for monopolar operation, it utilizes two electrodes: an active electrode and an indifferent electrode or ground plate. This concentrates the current density at the tip of the active (smaller) electrode. Monopolar radiosurgical technique is indicated for gross tissue manipulation in larger avian patients (>2 kg). The ground or indifferent electrode should be placed in contact with the patient as close to the surgical field as possible. Patient contact is improved with the application of a contact gel to the patient and ground. Alternatively, the ground plate may be permanently mounted under the surgery table and the patient placed

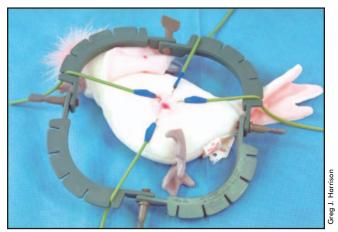

Fig 35.5 | Adjustable wound retractor frame and two tension bands hooked into one another. The location and tension on the band can be adjusted after inserting the hook into the surgical tissue. Then the band is slipped into a V-shaped slot in the frame at the ideal location and the desired pressure is applied.

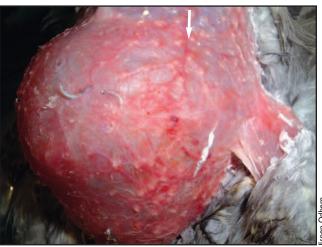

Fig 35.6 | The scar from a previous surgery is visible (arrow). There may be minor adhesions between skin and the abdominal wall; however, scar formation is generally minimal in the avian patient.

on a non-metal material such as a towel. Such material will prevent thermal burns to the dependent aspect of the patient. This is particularly important in thin patients with prominent bony sites that provide small conduction points that can generate high localized temperatures. The active electrode must be kept clean and free of char and debris. An excessive amount of char or debris will interfere with conduction, thereby creating drag through the tissue, inhibiting cutting action and increasing coagulation. This may delay wound healing and predispose the patient to wound dehiscence. Several types of electrode tips are commercially available. Ball-tipped electrodes create significant tissue destruction for fulguration and coagulation of large amounts of tissue; loop electrodes are useful to obtain tissue biopsies and surgically excise tissues; and fine wire electrodes are utilized for incisions. It is useful to have some tips (such as those used in dentistry) that function in a wet field for effective coagulation during hemorrhage.4,5

If cryosurgery is performed in conjunction with radiosurgery, it is important to note that radiosurgical tools will not work on frozen tissues.^{4,5}

Bipolar radiosurgical forceps are useful, particularly in small avian patients (<2 kg) (Fig 35.7f). These allow for hemostatic control at the tip without the use of a ground plate, as one of the tips serves as the active electrode and the other as the indifferent electrode. The current passes from one tip, the active electrode, to the other, the indifferent electrode, without passing through the entire patient. Closer proximity of the two electrodes alters the transmitted wave currents from those transmitted by monopolar electrodes, resulting in more precise control and less reflux hemorrhage. The cut settings are used for tissue incisions. The cut/coagulation settings are indicated for vessels that are difficult to

coagulate and for controlled cutting with coagulation properties (ie, as for organ biopsy). The coagulation settings are used for tissue fulguration. The material and design of the bipolar forceps, as well as proper calibration of the machine, determine the efficiency and performance of bipolar radiosurgery (Fig 35.7e). 4.5

Bipolar forceps may be used to make primary skin incisions, to incise through muscle with minimal hemorrhage, and to coagulate cutaneous blood vessels prior to incision with a scalpel blade or scissors. The skin may be grasped and elevated with thumb forceps, then incised with bipolar radiosurgical forceps. This incision is then extended by inserting the indifferent electrode of the bipolar forceps subcutaneously to the full extent of the desired incision. The forceps are then apposed with the skin between them and the incision performed is extended by dragging the tips over the full thickness of the skin. This will incise the skin and coagulate the blood vessels. Correct settings and proper use of radiosurgery does not cause discoloration of the skin lateral to the incision (ie, if the skin is discolored, tissue damage has occurred and primary intention healing is unlikely).5

Tissue incisions may be performed with monopolar tips as well. Wire-type tips may be used as an "electrosurgical scalpel". The current should be initiated prior to touching the tissue. Often, higher settings are necessary in birds as compared to mammals due to the lower water content of the skin, which may result in less coagulation of associated vessels and hemorrhage. Cutting ability may be improved in very dry skin by moistening the skin with saline.^{4,5} Feather follicles and their associated blood supply should be preserved whenever possible.⁵

When using the bipolar forceps for hemostasis, the forceps tips are relaxed as current is applied, providing a

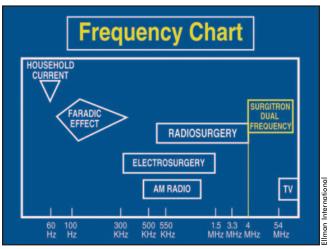

Fig 35.7a | Frequency chart.

Fig 35.7c | This unit has been modified to allow multiple bipolar or unipolar hand pieces with a flick of a switch.

Waveform	Setting	Properties	Uses
Fully-filtered Fully-rectified	Cutting	90% Cutting; 10% Coagulation	Incisions; Excision; Biopsy
Fully-rectified	Blended	50% Cutting; 50% Coagulation	Incision/Excision with increased hemostasis
Partially-rectified	Coagulation	10% Cutting; 90% Coagulation	Hemostasis
Poorly-rectified	Fulguration	Minimal Cutting/Coagulation	Superficial tissue destruction

Fig 35.7e | Versatility of radio wave surgery.

Fig 35.7b | The multifrequency radiosurgery generator for performing avian surgery with minimal hemorrhage.

Advantages of Radio Wave Surgery

- Excellent for both cutting and coagulation
- Rapid local hemostasis
- Very little tissue damage good cosmetic effect
- Tissue morphology preserved
- Sterilizes as it cuts
- Little postoperative pain
- Can be used with either general or local anesthesia
- Unit is lightweight and portable
- Different electrode tips for different applications
- Affordable

Fig 35.7d | Advantages of radio wave surgery.

Fig 35.7f | Various bipolar forceps. Left to right: The Harrison modification and three custom ring-tip models.

small gap between the two sides through which the radio current flows, thereby sealing the vessel. It is important to clean the forceps tips frequently. Accumulated blood and tissue can adhere to the clot and subsequently destroy it when the forceps are removed. Forceps tips are currently being developed with new materials that do not accumulate blood and tissue. When using the coagulation settings, the vessel may retract within the tissue due to vasospasm. This results in temporary hemostasis until the vessel relaxes, but hemorrhage may recur. A new modification that can be used with an endoscope has been developed (Figs 35.7g,h).

LASER SURGERY

Light Amplification by the Stimulated Emission of Radiation (LASER) relies on the production of electromagnetic radiation in response to photon emission by a lasing medium. Electrical energy excites a lasing medium (carbon dioxide, diode or argon) contained within an optical laser chamber, which, upon returning to a steadier electrical state, loses energy and generates photons in the form of electromagnetic radiation or light. These photons are directed from the optical laser chamber as monochromatic electromagnetic radiation transmitted via a series of lenses and delivery fibers in a focused and controlled laser beam. The type of lasing medium will alter the wavelength and frequency of the radiation. 38,69

Carbon dioxide and diode lasers are most commonly used in veterinary medicine. Both produce an immediate region of vaporization, surrounded by a zone of irreversible photothermal necrosis and a zone of reversible edema. Laser surgical incisions seal blood vessels, nerves and lymphatics for controlled hemostasis, analgesia and postoperative edema. Carbon dioxide lasers operate at a wavelength of 10,600 nm. They may be operated with a

focused beam, ideal for cutting, or a defocused beam, used for vaporizing tissue. They provide accurate, noncontact surgery with minimal tissue penetration and minimal collateral thermal injury (0.05-0.2 mm from the incision), as compared to the diode laser, which offers a zone of thermal injury of 0.3 to 0.6 mm from the incision. Thermal penetration is relatively superficial, penetrating only 50 to $100~\mu m$ in depth. 38,54,69

Diode lasers operate at a wavelength of 635 to 980 nm. They may be operated in direct contact with tissue (contact mode) or at a distance from tissue (non-contact mode). They have the ability to operate in a fluid environment (intestinal tract, fluid-filled coelom) and provide improved hemostasis, with the ability to coagulate blood vessels up to 2 mm in diameter, as compared to the CO₂ laser, which coagulates blood vessels up to 0.6 mm in diameter. Operation results in deeper tissue penetration and is relatively less precise. Diode lasers have been used for photocoagulation of retinal and other ocular tissues, chromophores enhanced tissue ablation and coagulation, laser welding and photodynamic therapy. In addition, the diode laser has the fiberoptic ability to operate with several endoscopes.^{38,54,69}

Laser is particularly useful for avian surgery, where hemostasis is of great concern. Surgical indications include salpingohysterectomy, orchidectomy, and limb amputation. It is also beneficial in the excision of granulomas, abscesses, and neoplasms. Endoscopic diode laser techniques provide minimally invasive access to several anatomic sites as well as endoscopic hemostatic control. Superficial lung and air sac granulomas within the cranial thoracic, caudal thoracic and abdominal air sacs have been successfully ablated with the 810-nm diode laser. 21,37,61

Fig 35.8a | Avascular necrosis of the phalanges can occur as a result of circumferential constriction due to fibers from cage bedding or as a condition of undetermined etiology. In the case of this bird, cloth fibers became entwined around the foot, leading to the visible digit swelling and potential for necrosis of the digits. Removal of the constricting fibers, appropriate topical antibiotics and bandage application are necessary to treat this condition.

Fig 35.8b | Manmade fibers tend to entrap digits. The threads are removed using 40x magnification and a bent-tip hypodermic needle as a cutting tool. When the constricting band is not accompanied by foreign material, treatment is similar to that described in Fig 35.8a. The circumferential bands may require debridement and suturing.

ILLUMINATION AND MAGNIFICATION

Avian surgery often requires delicate handling of small structures. Coelomic surgery is performed within a deep cavity, which obstructs visualization. Therefore, magnification and illumination equipment are essential (see Chapter 1, Clinical Practice). The ideal avian surgical light source provides optimum illumination with minimal heat transfer to the patient that may result in tissue dehydration and surgeon discomfort. (Ed Note: Although overbead lights that produce significant heat have been shown to be effective in helping to prevent hypothermia during avian anesthesia, forced warm air blankets also are effective and do not have the disadvantage of tissue desiccation and over heating of the surgeon). The small size of the avian patient necessitates intense light, precisely focused. This often requires changing the angle of the light to provide illumination and avoid shadows. A three-headed, flexible fiberoptic light source provides ideal illumination and the ability to change the focal area of the light. Often, 250-watt bulbs with no less than 20,000 lux are required. 1,4,5

Ocular head loupes and operating binoculars with a halogen light source also may be used for magnification and illumination. These allow the surgeon to set the light source on the surgical site, and magnification and illumination move with the surgeon. Operating microscopes are useful for avian patients, particularly those weighing less than 1 kg, and are advantageous for handling blood vessels in larger birds as well. An operating microscope with a lens objective approximately 150 power and a

12.5 power binocular objective is most useful.^{1,4,5}

A less expensive but also less effective option for increased magnification and illumination includes adjustable magnifiers with attached lights available for sewing and other home uses.

SUTURE MATERIALS AND ADHESIVES

Significant information is available regarding appropriate selection of suture material in veterinary and human medicine. Suture material utilized in birds must be minimally reactive and of an appropriate size. Tissue reaction to five suture materials has been evaluated in pigeons at 3, 7, 15, 30, 60, 90 and 120 days following implantation in the body wall. These include polyglactin 910, polydioxanone, monofilament nylon, medium chromic catgut and stainless steel. Pigeons developed a marked granulocytic inflammatory response to medium chromic catgut that diminished during the evaluation period. The suture was still present at the end of the study, indicating prolonged absorption of the material. Polyglactin 910 caused the most inflammatory reaction and was the most quickly absorbed, being completely gone by day 60. Polydioxanone, like polyglactin 910, is absorbed by hydrolysis. Unlike polyglactin 910, however, it caused minimal tissue reaction and absorption was occurring by day 120. Nylon and stainless steel are non-absorbable materials that caused minimal tissue reaction. However, the stiffness may make them mechanically irritating to surrounding tissues, and these were more often associated with hematoma, seroma and caseogranuloma formation.

This study concluded that chromic catgut should be avoided; slowly absorbed monofilament and synthetic materials absorbed by hydrolysis rather than proteolysis are recommended when prolonged wound healing is expected. Rapidly absorbed, braided, synthetic suture materials absorbed by hydrolysis are recommended when the benefit of rapid absorption outweighs the disadvantage of possible pronounced inflammatory reaction. Monofilament suture material has the advantage of minimizing trauma and cutting of tissue when compared to multifilament material. Taper-point needles are usually indicated in avian surgery, as compared to cutting needles to prevent tearing of tissues being sutured. Cutting needles may be useful for suturing thicker, tougher tissues such as the feet of larger species.^{4,5,10}

Cyanoacrylate tissue adhesives hold tissues in apposition to allow healing. The cyanoacrylate monomer is a liquid that polymerizes in a small amount of water present in tissues. However, it is important not to allow the acrylic to run between the apposed tissues, as this physical barrier will delay wound healing. One should be cautious when using these adhesives in the presence of anesthetic gases with which they are reactive. They may also cause ocular irritation and vomiting in avian patients. The fumes of some cyanoacrylate tissue adhesives may cause respiratory irritation as well.⁵

POSTOPERATIVE CARE

Postoperatively, the patient should be placed into a temperature-controlled incubator once it is able to stand without ataxia. Temperature should be set according to each individual's optimal requirements (27-30° C or 81-86° F for most psittacines) and supplemental humidified oxygen is beneficial to those patients at risk for hypoxia/hypercapnea during recovery.^{1,5,9,41}

Perches should be avoided until the bird has recovered sufficiently to balance and grip well. Once the patient can balance and grip, perches of low height are recommended. Food and water are not introduced until the patient has fully recovered to prevent regurgitation and aspiration. 1,5,9,41

The likelihood of postoperative self-trauma varies with the species, the individual patient and the surgical procedure performed. Avian patients generally do not traumatize their surgical incisions. Some clinicians advocate leaving longer-than-average suture ends to allow the bird to groom these as they would a feather. 1.5.9,41

Occasionally an Elizabethan or other collar is necessary to provide a mechanical barrier to self-induced trauma to the surgical site. In all cases where a collar is first applied, the bird should be monitored following the collar application. Agitation, depression, or inability to access food or water must be noted and corrected. If the bird can still traumatize the surgical site, collar adjustment also would be needed. Applying the collar prior to surgery may enhance acceptance of an Elizabethan or foam collar. This allows the bird to adjust to the collar, thus minimizing postoperative stress. Antianxiety or sedative medications such as diazepam may be given prior to collar application to decrease stress. Initially applying a small collar and increasing the size as necessary also may improve patient acceptance. Some birds will not tolerate restraint collars and customized body suits may be used to prevent self-trauma. 1,5,9,41

Soft Tissue Surgery

SKIN

Birds have a relatively thin, dry epidermis. In feathered regions, the skin may be only 10 cell layers thick. The dermis is loosely attached to the underlying muscle fascia with very little subcutaneous tissue except in the distal extremities where it is firmly adhered to the underlying bone.⁹

Constriction and Avascular Necrosis of the Digits

Avascular necrosis of the phalanges of the pelvic limbs may occur secondary to circumferential constriction caused by fibers, scabs or necrotic tissue. These constrictions compromise vascular flow to and from the distal phalanx, leading to edema and necrosis (Figs 35.8a,b). If detected early, the toe may be salvaged and amputation avoided. This condition is particularly common in pediatric patients. Proposed etiologies include low relative humidity, egg fiber-related strictures from hatching, septicemia and ergot-like intoxication. Increasing the environmental humidity and applying topical creams to promote hydration of the affected tissue may be effective in resolving early lesions. Eschars should be debrided and the digit cleaned and bandaged with a hydroactive dressing and allowed to heal by secondary intention. If tissue fibers are the inciting cause, a full-thickness linear skin incision should be made over the dorsal aspect of the constricted region. This area is then bandaged with a hydroactive dressing to prevent scab formation. Complete healing may require weeks to months. A circumferential excision of the constricted region followed by anastomosis of the skin may be performed. The constricted tissue is surgically removed with a scalpel blade. One to two subcutaneous sutures are placed to prevent excessive tension on the skin repair. The skin edges are apposed with several simple interrupted sutures placed superficially to prevent disruption of the vascular supply

by resulting eversion of the skin edges, which will delay wound healing. After the skin edges are apposed, 2- to 3-mm superficial release incisions should be made on the lateral and medial aspects of the digit at the site of the anastomosis. This will allow postoperative swelling to occur without constriction. A hydroactive dressing is applied and the digit bandaged. Magnification and illumination such as a head loupe or operating microscope are useful to visualize the fibers. 1,9

If the distal phalanx has developed complete avascular necrosis, amputation is necessary. Amputation should be performed just proximal to the proximal end of the necrotic tissue, where a good vascular supply still is present. An incision is made in the skin and subcutaneous tissue circumferentially. One or two sutures are placed in the subcutaneous tissue to relieve tension on the skin incision. Several simple interrupted sutures are placed in the superficial epidermis to prevent eversion of the skin edges, which will delay healing. The digit is bandaged and sutures removed in 10 to 14 days^{1,9} (see Amputation of Digit later in this chapter).

It is best to avoid the use of electrocautery or radiocoagulation to prevent damage to the minimal vascular supply of the digits. If a tourniquet is utilized to control hemorrhage, it should be used for only a limited time to avoid vascular compromise.^{1,9}

Passerines are prone to developing avascular necrosis of the pelvic limbs or digits due to entanglement with synthetic fibers such as nesting string. Microsurgical tools or a bent 25-gauge needle may be used to remove the constricting fibers. The tip of the needle can be used to elevate the fibers and the edge of the needle used to severe the material. A hydroactive dressing is applied and the area bandaged.1,9

Passerines also may develop constrictions secondary to hyperkeratosis or to the development of excessively large scales over the pelvic limbs and digits. Malnutrition and Knemidokoptes sp. infection have both been implicated as etiologies. These conditions may predispose the patient to Staphylococcus spp. infections. In most cases, skin lesions will resolve with correction of nutritional problems or treatment with ivermectin. In severe cases, it may be necessary to surgically debride these hyperkeratotic lesions or enlarged scales. Microsurgical instruments and magnification are useful for manipulating these small structures. Antibiotic emollient creams will soften and hydrate the skin while treating bacterial infection.^{1,9}

Feather Cysts

Feather cysts are usually formed as a result of injury to or deformation of the follicle.36b Direct trauma, mechanical and chemical cautery also are inciting causes.

Damage to one side of the follicle may result in asymmetrical feather growth. The developing feather may then grow in an arch back toward the body, forming a feather cyst (Figs 35.9a-i). Certain species of canaries, particularly the Norwich, Gloucester and their crossbreeds, may develop cysts as a result of abnormally formed feathers (Fig 35.10). These birds have been genetically selected to produce a downy, soft feather type that predisposes them to feather cysts. Malnutrition, viral, bacterial and parasitic infections may result in formation of feather cysts as well. 1,9,36b

The surgeon should examine the cyst to determine whether it contains a viable or devitalized feather. Perform an initial evaluation of the feather by making a small incision at the distal aspect of the cyst and examining the contents. Every attempt should be made to salvage viable feathers and tissue, particularly those involving tail rectrices and flight feathers.1,9

If excision is required, use of a scalpel blade offers the benefit of complete excision of the affected follicle without damage to adjacent follicles. Damage to adjacent feather follicles and/or their blood supply may disrupt feather formation and result in the formation of additional feather cysts. Radiosurgical fulguration has been performed successfully; however, the adjacent feather follicles may be damaged due to difficulty in controlling the extent of tissue destruction. Feather cysts typically have good vascular supply, so hemostasis is required.

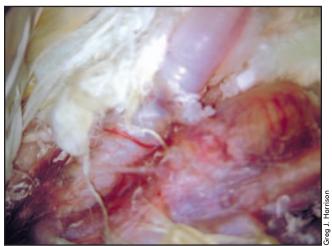

Fig 35.9a | Feather cysts in parrots usually form as a result of injury to the follicle. Direct trauma to the feather follicle can result in abnormal feather growth, thus promoting feather cyst formation. Improper wing trim, malnutrition, viral, bacterial and parasitic infections may result in the formation of poor-quality feathers that are easily damaged. This cyst has formed in the follicle of the dorsal major covert overlying primary remex VIII. While the cyst is dorsal, this follicle inserts on the ventral aspect of the major metacarpal bone. The underlying primary feather structures form the strongest boundary, so the cyst herniates dorsally. Approaching the cyst from this dorsal aspect fails to address the germinal tissue found at the point of insertion.

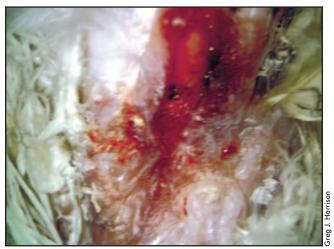

Fig 35.9b | Incising alongside the cyst using radiosurgery bipolar forceps.

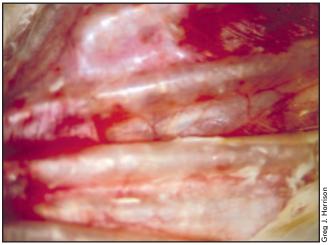

Fig 35.9d | Next the ventral surface of the wing is incised between primary VII and VIII, allowing access to the insertion of the cystic follicle on the ventral aspect of the metacarpal bone of the manus.

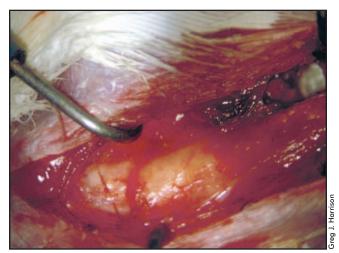

Fig 35.9f | Dissection of the follicular tissue. Retractor bands are repeatedly relocated to minimize trauma during cyst removal.

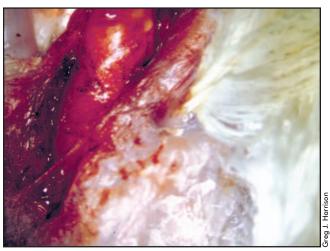

Fig 35.9¢ | Freeing the cyst dorsally from surrounding feather

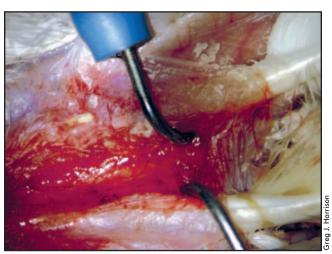

Fig 35.9e | Retractor bands used to improve the view and hold the unaffected follicular tissues out of the way of the radio wave's energy field to avoid damage. In Harrison's opinion, feather damage and failure to resect the point of insertion are the major causes of cyst surgery failure and cyst recurrence.

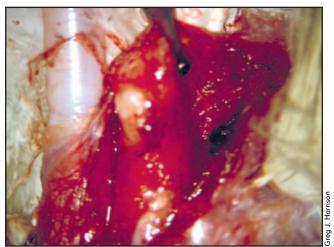

Fig 35.9g | The freed follicle is traced to its insertion and the nutrient vessel is coagulated.

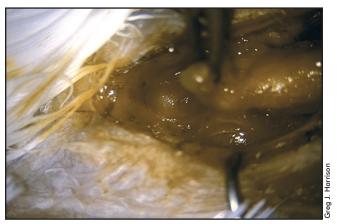

Fig 35.9h | The full cystic follicle is removed intact.

Fig 35.10 | Multiple feather cysts can occur on the body, either over a regional area or in a particular feather tract. Multiple cysts may be removed surgically using an elliptical or fusiform excision followed by primary closure with a simple continuous pattern using a monofilament suture.

A tourniquet, direct manual pressure applied to the surgical site or polysaccharide beadsd may aid in hemostasis. The site may be sutured or left to heal by second intention and bandaged with a hydroactive dressing. As adjacent feathers begin to regrow, debris should be removed carefully and the bandage changed frequently to prevent interference with developing feathers. Laser excision may improve hemostasis. Occasionally the cyst contains necrotic material but the follicular epithelium is not damaged, making new feather growth possible. In these cases, the follicle is incised and necrotic material removed. The follicle is then irrigated with sterile saline and the edges of the incision apposed. The site may be bandaged and local and/or systemic antibiotic therapy initiated. New feather growth must be carefully monitored for formation of cysts and disfigurement of new feathers. Feathers may fail to regrow if the epithelium has been severely damaged. 1,9

Occasionally a cystic follicle may be salvaged by marsupialization, particularly if there is a single cyst or a large follicle. An incision is made over the center of the cyst

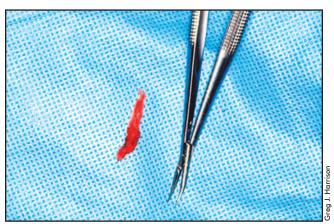

Fig 35.9i | Cyst removed intact and microsurgical needle holder.

with a scalpel blade parallel to the direction of feather growth. Hemorrhage is controlled with a tourniquet, manual pressure or by ligation. Radiocautery or chemical hemostatic agents may damage the epithelium and further damage the follicle. The contents of the cyst are removed and the lining sampled for cytology and bacterial culture. Redundant tissue is excised and the follicle irrigated with sterile saline solution. The margin of the cyst is then sutured to the adjacent skin using a simple continuous pattern with a fine monofilament suture. New feather growth must be carefully monitored for formation of further cysts or disfigured feathers. Feathers may fail to form if the epithelium is severely damaged.^{1,9}

Occasionally multiple feather cysts are present on the body, either over a regional area or in a particular tract. Multiple cysts may be removed using an elliptical or fusiform excision followed by primary closure with a simple continuous pattern using a monofilament suture material. Radical excision of an entire pteryla of affected feathers has been described. This is typically necessary in canaries. A fusiform incision is made around the affected pteryla. The primary vascular supply to the tract, and any large blood vessels are ligated or coagulated. The affected follicles are removed along with the surrounding skin. The remaining skin edges are apposed using a simple continuous pattern with a monofilament suture. 1.9

Feather cysts of the tail may be severe and disfiguring. Birds may traumatize these and develop secondary infections. Cysts can be excised as described previously. Amputation of the pygostyle is an option in those patients suffering from multiple cysts or those that have severe trauma to the surrounding soft tissues and underlying bone. This is performed by blunt dissection to the coccygeal vertebrae and disarticulation at the sacrococcygeal junction. Soft tissues are closed routinely and care should be taken not to enter the cloaca. Intraoperative hemorrhage and postoperative pain may be severe, and hemostasis and analgesia are crucial to a successful outcome.^{1,9}

Skin and Follicular Biopsy

Skin biopsy is indicated as part of a diagnostic process for dermatoses including feather dysplasia, featherdestructive behavior, auto-mutilatory conditions, ulcerative dermatitis, hyperkeratinization and feather loss (see Chapter 13, Integument). Selection of biopsy sites is crucial to accurate diagnostic results. A sample with an actively growing feather, an entire follicle and surrounding skin should be obtained for conditions affecting the feathers. The surgical site should be gently prepared, avoiding vigorous scrubbing that may irritate the skin and alter the histopathology results. The follicle is grasped with atraumatic forceps and the feather, follicle and skin excised with scissors or a blade. Disposable skin punch biopsy instruments also work well. Minimal pressure should be exerted with these biopsy punches due to the thin avian skin and absence of significant subcutaneous tissue. It is best to avoid cautery prior to excising the sample to prevent cellular and tissue changes to the edges, which may complicate histopathologic analysis. Radiosurgery may be used to control hemorrhage after the sample is obtained. Closure is routine.⁵⁷

Cranial Skin Defect Repair with an Advancement Pedicle Flap

Soft and hard tissue injury to the cranium may occur due to trauma from various sources including predator attack or attack from other birds, ceiling fan injuries and cage trauma. Species that commonly "flush" such as quail may be susceptible to cranial trauma if the caging does not have significant height to allow for flight. Soft tissue injuries that expose the cranium may result in chronic, non-healing wounds and devitalized cranial bone, which impedes formation of granulation tissue and epithelial migration. The skin covering the cranium is firmly adhered to the cranium. Primary and secondary closure of larger wounds may be difficult once skin edges have begun to fibrose. In addition, closure may create tension when apposing the skin edges, creating deformation of the eyelids and even exposure keratitis. Some wounds may be allowed to heal by second intention under a hydrophilic bandage material.^{27,73}

A pedicle advancement flap is preferable to simple closure to surgically resolve larger defects to the soft tissue covering the cranium. Advancement flaps remain continuous with the donor site thereby maintaining blood supply to the subdermal plexus within the flap. Pedicle advancement flaps have a greater chance of remaining viable, as compared to free grafts, particularly when the recipient site is poorly vascularized. In addition, full thickness skin and subcutaneous grafts will provide normal feather coverage if they contain pterylae.^{33,55,62-65,73}

Initially, the wound is assessed to determine the degree of

necrosis of the skin and cranial bone, and to examine the size of the defect to be repaired. The cranial skin is undermined and the skin edges are debrided, removing just enough skin to obtain a good vascular supply. If necessary, small rongeurs may be used to carefully remove devitalized bone; obviously, the cranium should not be completely penetrated. Initiating two skin incisions at the lateral aspects of the caudal end of the defect creates the pedicle flap. These incisions are continued caudolaterally over the cervical region. Divergence of the lateral incisions creates a wider base that increases the blood supply to the subdermal plexus, and compensates for the tendency for inadvertent convergence of the incisions when applying lateral skin tension where the skin is more mobile. 33,55,62-64 These incisions should be made with either a scalpel blade or sharp surgical scissors to maintain integrity of the ends of the blood vessels that will be advanced cranially. The pedicle is undermined bluntly to prepare the flap for advancement. The skin flap is advanced rostrally and the skin edges apposed with small monofilament suture in a simple continuous or interrupted pattern using a taperpoint needle.27,73

If the defect is too large to correct with a single surgery, the initial procedure should close as much of the defect as possible and the remaining defect can be covered with a hydroactive dressing. A second surgical flap may be created or a staged closure of the defect using horizontal mattress sutures may be performed to completely repair the defect.

Repair of Ulcerative Lesions of the Sternum (Carina of the Keel)

Ulcerative lesions to the carina of the keel are most often traumatically induced (see Chapter 1, Clinical Practice). Thermal burns, foreign bodies, poxvirus, mycobacteriosis or other stressful situations such as heat and overpopulation have been implicated as well. Improper wing trimming, particularly in heavier bodied birds (African grey parrots and Amazon parrots) may cause the bird to impact the floor when it attempts to fly. This trauma may create a bruise or a laceration of the skin over the carina. Scars from previous traumatic episodes are often evident upon routine physical examination. Auto-mutilation of the tissue overlying the carina may occur as well. Secondary bacterial infection, often involving anaerobes, is common in this location.³⁹

Traumatic lesions of the carina often heal readily if the patient is prevented from falling and re-injuring the site. Conversely, repeated trauma and/or auto-mutilation may cause more severe and chronic lesions. These lesions may require extensive surgical debridement. Extensive lesions may prevent primary closure and may heal by second intention.

Surgical correction is accomplished with the patient in dorsal recumbency. The feathers are removed in a 2-cm diameter around the circumference of the wound and the area surgically prepped. The skin and subcutaneous tissues are debrided until healthy tissue is encountered. It may be necessary to debride devitalized pectoral muscle and affected portions of the carina of the keel. Radiosurgery may be used for hemostasis. Tissue and bone samples should be submitted for bacterial culture and histopathologic examination. The elevated origins of the pectoral muscles are sutured together over the keel or anchored to the cartilaginous portion of the keel in an interrupted horizontal mattress pattern with absorbable monofilament suture. The skin is closed in a simple interrupted or continuous pattern with monofilament suture. There is often considerable tension on these incision sites, therefore, it may be necessary to place tension-relieving sutures lateral to the incision. One method described involves placing interrupted horizontal mattress sutures through the skin and pectoral muscle tied over gauze sponges just lateral to the medial incision. The wings may be bandaged to the body to prevent extension and movement that would place additional tension on the suture site, and a restraint collar or body suit is usually necessary if auto-mutilation has occurred. Defects that are too large to close surgically may heal by second intention. Gentle irrigation and frequent bandage changes with a sterile hydrophilic dressing will assist in healing.39

Xanthoma

Xanthomatosis results from the accumulation of lipidladen macrophages, giant cells, free cholesterol and variable degrees of fibrosis. Xanthomas often occur at the distal wing, but have been found in other locations as well. These masses may be locally invasive and wide margins may be necessary to completely excise and prevent recurrence. Some birds may mutilate these lesions, causing ulceration and secondary infection. Elevated serum cholesterol, trauma and genetic predisposition in some species have been implicated in the formation of xanthomas. Dietary correction may be curative in some species and in some individuals. However, very large, painful, hemorrhagic or infected xanthomas often require surgical resection.

Masses may be removed with bipolar or monopolar radiosurgery, taking care to avoid damage to remaining feather follicles and their blood supply. The site may be closed if there is enough remaining tissue or allowed to heal by second intention and bandaged with a hydroactive dressing (Figs 35.11a-g). If extensive subcutaneous tissues and bone are involved, amputation of the affected area may be necessary.9

Uropygial Gland

The uropygial gland is located dorsal to the tail. It is absent in Amazon parrots (Amazona spp.) and the hyacinth macaw (Anodorbynchus byacinthinus) and may be reduced in size in some cockatiels. Disease of this gland and/or its papillae is not uncommon and surgical correction may be necessary. Absence of papilla feathers may indicate a problem with glandular function. Left untreated, a gland may rupture, causing inflammation and significant scar tissue formation. Simple impaction of the gland may respond to medical therapy and gentle expression of the contents. If the impaction cannot be alleviated by conservative therapy, small incisions may be made over the affected lobe(s) of the gland, the contents expressed, and the gland irrigated with saline. Antibiotics and analgesics may be indicated during recovery.9 Neoplastic conditions of the uropygial gland with secondary infection occur with some frequency (see Chapter 13, Integument).

Chronic impaction and/or infection unresponsive to medical therapy and neoplasia of the uropygial gland may require surgical removal of the affected gland. The patient is placed in lateral or semi-ventral recumbency. Intermittent positive pressure ventilation and close monitoring of respiration is necessary when positioned ventrally to ensure movement of the sternum is not reduced and respiration not impaired. The head may be elevated and a pad may be placed under the tail, with the tail rectrices taped in place to elevate the sacrum and improve exposure and visualization of the uropygial gland. The surgical site is aseptically prepared. The gland is bilobed and each lobe receives its vascular supply from a vessel that branches at the cranial, middle and caudal portions of the gland. These vessels and other surrounding vessels require ligation or bipolar radiocoagulation. The gland may extend deep to the synsacrum and caudally to the insertion of the tail feathers.9

A fusiform incision is made via unipolar or bipolar radiosurgery around the circumference of the gland. This is initiated caudal to the papilla and continued craniolaterally along both sides of the gland. Dissection of the gland is initiated at the caudal aspect of the gland and extended circumferentially and cranially until the gland is removed. Mosquito hemostats or thumb forceps may be used to apply gentle traction on the gland, facilitating removal. The strongest attachments are associated with the muscle fibers at the cranial border of the gland. Hemorrhage must be strictly controlled by radiocoagulation, manual pressure and/or hemostatic products.9 The deeper fascia is closed with absorbable monofilament suture in a simple continuous or interrupted pattern, depending on the amount of tension present. Subcutaneous and skin closure is routine. Extensive tissue trauma, neoplasia or

Fig 35.11a | Xanthomas often occur at the distal wing, but have been found in other locations. Note the balding plantar foot patterns and the discoloration of the feathers. These are indicative of malnutrition and related disorders.

Fig 35.11b | Xanthomas that are well demarcated and/or pedunculated may need to be excised.

Fig 35.11c | Xonthomas that are closely associated with feather follicles may be excised, being cautious not to cause follicle damage.

Fig 35.11d Removal of such well-defined distal wing xanthomas can be performed by making a small skin incision and gently teasing the contents out with a sterile cotton swab.

Fig 35.11e | Hemorrhage can be controlled with a bipolar or monopolar radiosurgical unit.

Fig 35.11f | After using radiosurgical hemostasis allow a few moments to make sure no oozing occurs.

Fig 35.11g | The skin is closed in a simple interrupted suture pattern with a monofilament suture.

rupture of the uropygial gland may require additional dissection and debridement. An additional caudal incision perpendicular to the dorsal midline incision may be necessary. If the remaining defect is too large to allow full closure, staged closure or healing by second intention may be necessary. Any open defects should be bandaged under a hydroactive dressing to promote granulation and prevent exposure. Antibiotics and analgesics should be

administered as appropriate to each patient. Dehiscence, damage to the follicles of the rectrices and infection are potential complications (Figs 35.12a-e).9

Pododermatitis

Treatment and surgical intervention in severe presentations of pododermatitis are outlined in Chapter 13, Integument.

Fig 35.12a | The feathers of the uropygial gland and the feathers of the skin dorsally should be removed prior to surgical removal of the gland. Care must be taken when removing these feathers to prevent gland rupture or hemorrhage. Once the feathers of the papilla are removed, material may drain from the gland. This material will need to be cleaned and a gentle routine surgical scrub performed prior to surgery. A fusiform incision is made around the uropygial gland papilla, remaining dorsal to the tail feathers.

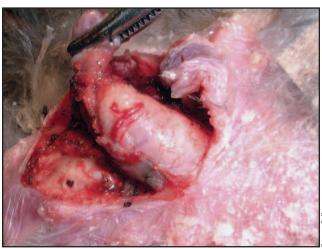

Fig 35.12b | The tissues underlying the skin are gently dissected and the skin flap is gently reflected dorsally and cranially. Hemorrhage is controlled by coagulation with a bipolar radiosurgical unit. The difference in the appearance between the left (impacted) and the right (non-impacted) side of the gland are apparent in this picture.

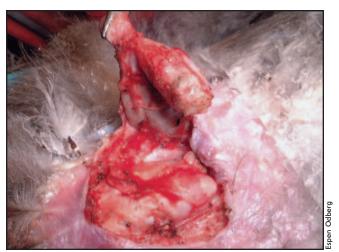

Fig 35.12c | The largest vessels of the uropygial gland are located on the cranial aspect of the gland along the muscular attachments. By utilizing the duct as a handle and working caudal to cranial, the underlying vessels can be visualized and coagulated with the radiosurgical unit. Removing the gland requires careful dissection and thorough examination for bleeding vessels.

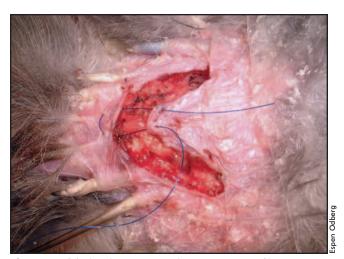

Fig 35.12d | The skin is apposed using 5-0 monofilament nonabsorbable suture. Beginning the sutures in the middle of the incision will allow for easier alignment of the skin flap.

Surgery of the Upper Respiratory System

RHINOLITH REMOVAL

Birds may develop rhinoliths secondary to chronic rhinitis and malnutrition. These masses are often formed from desiccated secretions and debris and cause a physical obstruction to respiration. The nares and opercula may become severely eroded and disfigured and damage is often permanent. Clinical signs include sneezing, upper

respiratory sounds, inflation of the associated infraorbital sinus, nasal discharge and picking at the affected nares with a toenail. The nares will appear impacted with material, but it is important to recognize the normal anatomy and not mistake the operculum for abnormal material (Figs 35.13a,b). A strong light source, magnification and gentle probing may be required to identify a small rhinolith (Figs 35.14a,b). Surgical head loupes with halogen light sources are particularly useful. 1,9,71

Nasal tissues are friable and vulnerable to traumatic

Fig 35.12e | The appearance of the incision following resection of the uropygial gland and completion of the skin closure (see Fig 35.12d).

probing, which will also predispose the mucosa to infection. Prior to attempting removal, warm saline drops should be applied to the affected naris and associated rhinolith. This will ease removal and decrease trauma to the associated tissues. A stainless steel aural curette may be used to gently elevate and remove the mass from the naris. A lacrimal cannula may be used in smaller avian patients such as budgerigars and passerines. Samples should be obtained for cytology, and bacterial and fungal culture. The nares should be flushed with a disinfectant (eg, dilute chlorhexidine or F10 solution) after removal of the bulk of the mass to remove any small pieces or material and to assist in resolution of any pathogens.⁷⁹ Appropriate antibiotic or antifungal therapy should be initiated and subsequent flushing performed. Malnutrition should be treated through diet correction. Proper air filtration, humidification and frequent bathing are necessary to prevent recurrence. The rest of the respiratory system should be thoroughly evaluated to identify other concurrent disease. 1,9,71

INFRAORBITAL EXPLORATION AND TREPHINATION

Infraorbital sinusitis is a common disease in pet birds. This may lead to rhinitis, conjunctivitis, lacrimal infections, and if left untreated, may result in abscess and necrosis of the infraorbital sinus and osteomyelitis of the surrounding bone. Clinical signs include sneezing, nasal discharge, picking at the nares and choana with the toes, inflation of the infraorbital sinus, periorbital swelling and conjunctivitis. Hypovitaminosis A, low environmental humidity and environmental inhalant irritants may predispose birds to secondary bacterial and fungal infections. A sinus flush with sterile, non-bacteriostatic saline may be performed to obtain samples for cytology, and

bacterial and fungal cultures.^{1,9,71} If flushing of the sinus via the nares and other medical therapy (eg, nebulization) is not effective in establishing drainage, a surgical approach may be used.

To access the infraorbital sinus, the patient is placed in dorsal recumbency and ophthalmic lubricating ointment applied to both eyes. An incision is initiated at the rostral aspect of the infraorbital diverticulum of the infraorbital sinus midway between the eye and the external nares. It is continued caudally, staying parallel with the lateral aspect of the head. Caution must be taken not to penetrate the ocular orbit located caudally. This area is extremely vascular and hemorrhage may be controlled by the use of a laser, radiosurgery, direct pressure or commercial hemostatic products. The sinus must be thoroughly explored, as mucoid, purulent or caseous material may be located within the nasal cavity, within the beak, and between the sinus and the nasal cavity caudal to the turbinates. The sinus cavity should be well irrigated with sterile saline prior to closure and it may be necessary to remove affected periorbital bone. Closure is achieved in a simple continuous pattern with monofilament suture. 1,9,71

Supraorbital trephination may be necessary to gain access to the dorsal and caudal areas of the infraorbital sinus, which cannot be accessed with nasal flushing and sinus aspiration. This will allow direct irrigation of these affected areas. The skin is incised to expose the frontal bone. Holes are made in the bone with a sterile rotary tool just above the eye. These holes are angled toward the midline. Cortical bone is removed until cancellous bone above the sinus is visible. Drilling is then advanced and widened to an appropriate diameter. Samples are obtained for cytology and culture, and the sinus irrigated with an appropriate solution such as saline, chlorhexidine, F10, water-soluble antibiotics and/or antifungals. The solution should pass through the choana and into the oral cavity to confirm that the trephination is accurately located. With this irrigation, fluid will enter the oral cavity; therefore, the patient should be intubated and the head positioned to allow the fluid to exit the mouth. To prevent aspiration, the oral cavity may be packed with an absorbent material to collect any excess fluid. The trephination site should be irrigated often and the site may need to be reopened, as healing occurs quickly. This procedure may be performed bilaterally, particularly in species such as passerines, in which the right and left infraorbital sinuses do not communicate. Once therapy is no longer required, the sites will heal quickly with minimal scarring. 1,9,71

CHOANAL ATRESIA

Choanal atresia has been reported in African grey parrots

Fig 35.13a | Normal naris in a lovebird.

Fig 35.14a | An African grey demonstrates a mild or early stage of accumulation of debris on the operculum. Left untreated, this condition would likely progress to a rhinolith.

Fig 35.13b | Avian patients with malnutrition and subsequent squamous metaplasia and chronic respiratory infections can develop rhinoliths. Erosions of the operculum and nares may result in permanent disfigurement of the nostrils, as shown in this lovebird.

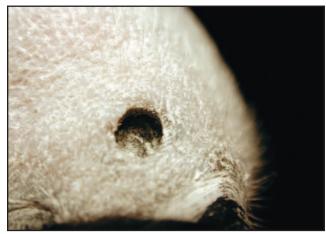

Fig 35.14b | A normal naris in an African grey on a formulated diet. Normal powder down is naturally coating the operculum, illustrating the need for showering.

(Psittacus erithacus erithacus) and one white cockatoo (Cacatua alba). The choana may either be entirely absent or there may be a membrane present that prevents communication between the nasal cavity and the pharynx. Rhinography and an endoscopic examination reveal this lack of communication. 14,36a,71

A choanal communication may be created with the nasal cavity by hand-drilling a 1/8- or 7/64-inch Steinmann pin into each naris, through the nasal choanae, to enter the choana. An 8 French red rubber catheter is then passed from one naris, through the choana, and exited through the other naris. Previously cut slits in the tubing allow mucus to drain. This creates a loop of rubber tubing across the cere with each end passing through the nares to the choana. The ends are tied and secured behind the head. The tube is left in place for 4 to 6 weeks to allow formation of a permanent communication. Nasal

flushes with saline are performed twice daily for 7 to 10 days to prevent mucus from occluding the holes (Figs 35.15a-n).14,36a,71

RUPTURE OF THE CERVICOCEPHALIC AIR SAC

Hyperinflation of the cervicocephalic air sac has been attributed to chronic infection and/or inflammation, while rupture may occur with trauma, with the former condition being more common. Location of the site of occlusion of normal air flow or rupture of the air sac in traumatic cases may not be identifiable. Smaller avian species typically suffer from generalized overinflation or rupture, while hyperinflation or subcutaneous emphysema is generally confined to the dorsum of the neck. A cutaneous Teflon stent may be surgically implanted at the highest point of the head to allow air to escape. The stent must be carefully monitored for occlusion with debris. 1,9

A skin incision is made just large enough to insert a 5-mm Teflon stent. Sutures are pre-placed in the four pairs of holes in the flange of the stent. The suture enters the one hole from the external side, doubles back, and passes through the other hole from the lateral side. Once all four sutures are placed, the stent is implanted. A 22-gauge needle is inserted through the skin at the proper location for one end of the suture material to be inserted through the needle to be exteriorized through

the skin. This procedure is repeated for the remaining three sutures and the sutures tied in place. The stent may become occluded and may require cleaning with a swab or needle. Occasionally the cervicocephalic air sac may be so excessively hyperinflated that it may interfere with prehension of food or even traumatize the cornea. Excess redundant skin may require resection after releasing the excess air and deflating the air sac.^{1,9}

Fig 35.15a | An African grey with epiphora from choanal atresia.

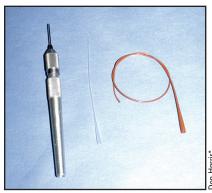

Fig 35.15b | (From left to right) 0.065 K-wire, with or without the chuck, 3.5 French closed-end tomcat catheter, No. 5 French rubber feeding tube.

Fig 35.15c1,2 | To access the nasal passageway, the K-wire pin must be introduced in a direction perpendicular to the long axis of the head. The initial approach is the most important step, as it determines the site of choanal perforation.

Fig 35.15d | The tip of the pin (with or without the chuck) is introduced through the nostril beneath the turbinate. While maintaining contact with the ventral surface of the nasal cavity, the pin is angled medially until the ventral midline of the nasal cavity is encountered. The exact ventral midline must be located blindly - based on "feel." In birds that do not have an osseous blockage, the membrane can be determined by some "give" in the distal end of the pin as the midline is slowly approached. Or, instead of a soft membrane, you may encounter a "slot" in the bony tissue into which the pin tends to slip. At the midline of the ventral aspect of the nasal cavity, the pin is directed with minimal pressure and rotation to puncture through into the oral cavity.*

*Figs 35.15a-n used with the permission from Zoological Education Network.36a

Fig 35.15e | When the perforation has been made, the Kwire is removed, and a tomcat catheter is inserted into the naris and passed in the same direction into the oral cavity.

Fig 35.15f | The tomcat catheter is introduced into the oral cavity with a hemostat which is used to pull it through the newly created opening.

Fig 35.15g | When the catheter has been pulled most of the way through, the proximal end must be trimmed to fit through the nasal passage.

Fig 35.15h | The distal end of the feeding tube is introduced into the proximal end of the catheter.

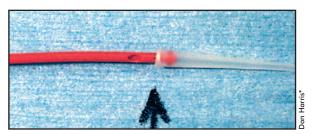

Fig 35.15i | A mark is made at the point where the two join together snugly. The feeding tube is removed and the catheter is trimmed at that point.

Fig 35.15[1,2 | After the connection has been made, the catheter is used to pull the feeding tube through the nasal perforation and into the oral cavity.

Fig 35.15k | After one end of the feeding tube is introduced into one nostril, the procedure is repeated by introducing the other end of the feeding tube into the other nostril. The free ends of the tube are pulled through so that the middle of the feeding tube is retracted onto the dorsal surface of the cere.

Fig 35.151 At the point where the tube exits one nostril and enters the other, the tube itself must be trimmed to allow the passage of mucus from the nasal cavity externally. If this is not done, the sinuses fill with nasal mucus and the tube would need to be removed, drained and reinserted.

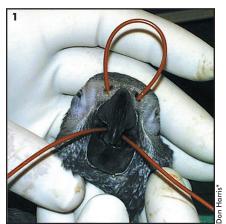

Fig 35.15m1,2 | The feeding tube actually creates a figure 8 configuration where one end enters the left nostril and comes out the right side of the mouth; the other end of the feeding tube enters the right nostril and exits the left side of the mouth. The ends are tied behind the bird's head.

Fig 35.15n | A chin strap can be devised to help hold the tube in place.

*Figs 35.15a-n used with the permission from Zoological Education Network.36a

Placing a one-way valve connecting the cervicocephalic air sac to the clavicular air sac may also be used to treat rupture of the cervicocephalic air sac. An approach is made through the left lateral thoracic inlet. The tube is inserted into the hyperinflated air sac, directed caudally along the esophagus, through the thoracic inlet, and into the cranial aspect of the clavicular air sac. The tube is sutured to the *longus coli* muscle to prevent migration, but no attempt is made to suture the air sac around the tube. Skin closure is routine. This method does pose a risk associated with leaving a foreign object in the body. The risk/benefit ratio should be considered prior to surgery, as many birds function well with a persistently hyperinflated cervicocephalic air sac.^{1,9}

Air sac hyperinflation may be treated by an alternative procedure that may be used alone or in combination

with those previously described. This procedure is particularly useful if the hyperinflated air sac poses a mechanical obstruction to respiration, food intake and physical movement. The air is removed by making a small incision in the overlying skin and air sac, thereby deflating and collapsing the air sac. Redundant skin and air sac are excised, and the skin and air sac sutured to the underlying tissue in several places to prevent extensive re-inflation. The surgical site is closed with a simple continuous pattern using monofilament suture. Traumatically induced subcutaneous emphysema may be alleviated by surgically incising the site to remove the excess air from under the skin.

Although postsurgical subcutaneous emphysema is possible, it is uncommon even in birds that have undergone extensive surgery to the air sacs and associated bone.^{1,9}

Thoracic Surgery

TRACHEAL OBSTRUCTION

Foreign material such as seeds, granulomas, inflammation, scarring post-trauma, or concretions of epithelial cells and mucous may occlude the trachea or syrinx, resulting in respiratory distress. Clinical signs include respiratory distress, dyspnea and vocal change. A history of recent anesthesia and intubation should raise concern regarding iatrogenic tracheal trauma, particularly if the endotracheal tube cuff was inflated. Foreign material may be visible in the trachea by wetting the overlying feathers with alcohol and transilluminating the trachea. Often foreign material is located at the syrinx or main bronchi, and therefore may not be visible during an examination. The trachea also may be assessed and obstruction diagnosed with both radiographs and tracheoscopy. 9,14,18,71

Treatment varies with the severity of the disease, size of the patient and anatomy of the trachea. Certain species such as swans and cranes possess elongated, tortuous tracheas with portions being located within the thorax, making access to the distal trachea difficult. Emergency treatment includes oxygen supplementation and possible placement of an air sac cannula to create a patent airway and stabilize the patient prior to further care. Please refer to Chapter 7, Emergency and Critical Care for a complete description regarding placement of air sac cannulas in birds. An appropriately sized needle may be temporarily placed through the trachea just distal to the foreign body or granuloma to prevent distal migration of the obstructing material, particularly during endoscopic retrieval or debridement. In certain avian species, the pessulum, a midline syringeal cartilage, may be present, which may impede access to a syringeal or bronchial foreign body or granuloma. 1,9,14,18,71

Many foreign bodies may be retrieved and infectious or inflammatory granulomas may be debrided via tracheoscopy. This is an effective and minimally invasive procedure that should be pursued prior to tracheotomy. Establishment of a patent airway is necessary for respiration and anesthesia. An air sac cannula should be placed until the obstruction is removed. If the obstruction is due to a granuloma or inspissated material and mucus, a small tube such as a urinary catheter or an endotracheal tube may be advanced to the point of obstruction and used to attempt aspiration of the foreign material. Samples should be submitted for cytology, bacterial and fungal cultures. Appropriate antibiotics, antifungals, and nebulization should be continued post-operatively until resolution is achieved. 1,9,18,71,84

If unsuccessful, or if the patient's trachea is too small to allow passage of an endoscope, a tracheotomy may be

necessary. The patient is placed in dorsal recumbency and the area from the mandible to 1 to 2 cm distal to the thoracic inlet is surgically prepared. A transverse tracheotomy of approximately 50% of the tracheal circumference is performed on the ventral tracheal surface. The entire tracheal diameter should not be transected in order to maintain its anatomic alignment, reduce tension on the surgical closure and prevent disruption of the vascular supply. Stay sutures are placed around the tracheal rings adjacent to the tracheotomy site to atraumatically manipulate the trachea. Foreign material may be grasped and removed, gently debrided, suctioned, or material cranial to the incision may be pushed cranially to exit through the glottis. Simple interrupted sutures are preplaced to incorporate one to two tracheal rings on each end of the incision using small, absorbable monofilament suture. Knots are tied external to the tracheal lumen to prevent granuloma formation intratracheally. If the trachea completely separates during the procedure, an anastomosis may be performed in the same fashion, closing the entire circumference of the trachea. Soft tissue, subcutaneous and skin closures are routine (Figs 35.16a-f). 1,6,7,9,14,18,71,84

Due to the predilection of masses and foreign bodies to be located at the level of the syrinx, surgery is often focused on the thoracic inlet. An operating microscope or halogen-illuminated magnification head loupe is necessary for optimal visualization. The patient is positioned in dorsal recumbency and gas anesthesia is delivered via an air sac cannula. A sterile swab or feeding tube should be placed in the esophagus to facilitate identification and avoid iatrogenic trauma. The skin is incised from the right clavicular-sternal junction to the clavicular-coracoid junction just lateral and ventral to the crop. The overlying skin is gently elevated from the crop and the surrounding tissues bluntly dissected from the crop to avoid tearing the crop or transecting surrounding blood vessels. Once the crop is freed from its clavicular attachments it should be reflected to the left. The trachea is identified by its complete cartilaginous rings. The sternotracheal muscles traverse obliquely and are transected near their caudolateral tracheal attachments. A large blood vessel lies between the muscle bellies and should be coagulated prior to transection of the muscles. 1,6,7,9,14,18,71,84

Once access to the thoracic inlet has been achieved, it is helpful to elevate the cranial end of the restraint board to improve visualization deep into the thoracic inlet. The interclavicular air sac is bluntly dissected. A blunt hook is looped under the syrinx at the tracheal bifurcation and gently pulled cranially for better visualization. Tracheotomy, foreign body retrieval, granuloma debridement and closure are as described previously.9

Fig 35.16a | Surgical preparation for tracheal surgery involves placing the patient in dorsal recumbency. The area from the mandible to 1-2 cm distal to the thoracic inlet is surgically prepared by removing the feathers and scrubbing the skin with an appropriate presurgical scrub.

ence.

Fig 35.16c | Care should be taken not to exceed 50% of the tracheal circumference with the tracheotomy incision. This is critical in order to maintain anatomic alignment, reduce tension on the surgical closure and prevent disruption of the vascular supply.

Fig 35.16d | A small-diameter endoscope can be inserted into the trachea to identify foreign material.

Fig 35.16e | A small-diameter suction tip, feeding tube or endoscope can be inserted into the trachea and gentle suction applied to remove any aspirated material.

Fig 35.16f | Simple interrupted sutures are pre-placed to incorporate one or two tracheal rings on each end of the incision using small, absorbable monofilament material. Knots are tied external to the tracheal lumen to prevent granuloma formation intratracheally. If the trachea completely separates during the procedure, an anastomosis may be performed in the same fashion, closing the entire circumference of the trachea.

Certain species such as Amazon parrots, small macaws and smaller birds have shorter primary bronchi, and cranial retraction of the syrinx may result in avulsion of the bronchi from the lung. Therefore, a left lateral approach to the syrinx may be preferable. The patient is positioned in right lateral recumbency. An incision is made over the second and third ribs. These ribs are exposed by blunt dissection and transected at both ends to allow complete removal. This will expose the cranial portion of the lung. The cranial portion of the lung is gently dissected and reflected from its attachments with a moistened cotton-tipped applicator. The jugular vein, pulmonary artery and branches of the subclavian artery are then identified and should be avoided. Dissection between these vessels is performed to access the syrinx. A 2- to 3-mm incision is made in the syrinx using bipolar radiosurgical forceps at the junction with the left primary bronchus. A foreign body may be removed or granuloma debrided via tracheoscopy, suction or gentle manual removal. The syringeal incision heals by second intention. The lung is repositioned into its normal anatomic position and the ribs are not replaced. Soft tissue, subcutaneous and skin closure are routine. 1,9,71

PNEUMONECTOMY

Surgical removal of lung tissue is indicated for biopsy and for removal of abscesses, granulomas and primary lung neoplasia. Biopsy of lung tissue may be performed by endoscopy. This is an effective and less invasive procedure if the desired site for biopsy is accessible via laparoscopy. There is no discrete pleural space in birds and the visceral and parietal pleura are in close approximation. The dorsal pulmonary parenchyma is contoured tightly to the ribs and intercostal spaces, which facilitates the surgical approach. The avian lung is more vascular and the intrinsic clotting mechanism appears to be less efficient, as compared to mammals, therefore, hemorrhage is a concern.1,9

The patient is placed in right or left lateral recumbency, depending on the site desired for biopsy, and the surgical area prepared routinely. A lateral celiotomy is performed. The lungs may be approached through the caudal thoracic air sac or through the intercostal space by removing one or two ribs. The affected lung tissue is carefully elevated using a sterile, moistened cottontipped applicator and isolated using vascular or hemostatic clips. The tissue is excised between the clips, leaving them with the viable portion of the lung for hemostasis. No studies exist to determine the amount of lung tissue that may be safely removed or the physiologic effects of pneumonectomy. However, clinically, patients appear to recover well after partial pneumonectomy. Closure includes apposing the intact ribs with stainless steel suture, cerclage wire or non-absorbable monofilament suture. If a caudolateral thoracotomy has been preformed and a portion of the last rib had to be removed for maximum exposure, resulting in unsuitable tissue to close the musculature, a stitch surrounding the remaining rib, passing caudally to and around the ipsilateral pubic bone can produce the tension needed to bring the tissues into apposition. Skin closure is routine. 1,6,7,9

AIR SAC GRANULOMA RESECTION

Air sac granulomas are usually identified via radiographs, endoscopy or occasionally by ultrasound. If resection is indicated, a celiotomy is performed based on the relative location of the granuloma (see Celiotomy under Surgery of the Gastrointestinal Tract below).

Surgery of the **Gastrointestinal Tract**

ORAL CAVITY

Keratinized cysts, abscesses, oral papillomas, neoplastic masses and traumatically induced wounds may be found on the tongue, choana, glottis, submandibular cleft and salivary glands. Chronic vitamin A deficiency may result in the accumulation of keratin within cyst-like structures and the formation of caseous abscesses in the oral cavity, submandibular skin and salivary glands.73 These may interfere with respiration and swallowing. If respiration and food intake are not compromised, it may be beneficial to perform a fine needle aspirate to obtain samples for cytology, bacterial and fungal cultures. Appropriate antibiotic, antifungal and parenteral vitamin A therapy may reduce the size of the abscess and promote encapsulation, thereby reducing the size and vascularity of the mass to be removed. Medical treatment listed previously, including supplementation with beta-carotene, has occasionally been reported to resolve these abscesses. 1,9,73

Submandibular abscesses may be resected by incising the skin overlying the masses on the ventral neck. Abscesses within the oral cavity may be less accessible and extremely vascular. It is important to intubate these patients to prevent blood and debris from entering the airway, and pre- and postoperative endoscopic examination is helpful to fully assess the oral cavity and choana. Radiosurgery or laser may be used to incise the abscess and to control hemorrhage. The contents of the abscess are removed and the site irrigated with an appropriate disinfectant. If present, the capsule should also be resected if this can be accomplished without clinically significant hemorrhage. Samples are collected for cytology, histopathologic examination, bacterial and fungal cultures. The remaining defect is left to heal by second intention. Abscesses or cysts located on the palatine area and choanal slit may be removed in the same manner. This area is extremely vascular and hemostasis is crucial to prevent severe hemorrhage. Some surgeons recommend temporary ligation of the palatine arteries during the procedure. 1,9,73

Papillomatous masses may be removed from the choanal slit, glottis or pharynx with radiosurgery, laser or cryosurgery. Removal with chemical cauterization must be carefully controlled to prevent severe damage to adjacent tissues. Excision is usually not curative and recurrence is common. Papillomatous masses are often located in other regions of the gastrointestinal tract and cloaca. Hepatic and pancreatic carcinoma are associated with papillomatosis. The reader is referred to other sections of this text for a thorough description of papillomatosis and associated disease conditions (Figs 35.17a-c, 35.18a-c). 1.9,73

Traumatic injuries to the tongue may result in significant hemorrhage, pain and failure to eat. If topical anticoagulants and chemical cautery fail to control hemorrhage, a mattress suture may be placed with an absorbable monofilament suture. The knot of the ligature is placed on the ventral surface of the tongue.⁷³

Neoplasia of the tongue has been reported. These masses may be removed by radiosurgery or laser.⁷³ Complete excision with adequate margins may be difficult and it may be beneficial to ablate the surrounding tissue. A feeding tube or frequent tube-feeding may be necessary for alimentation.

PHARYNGOSTOMY

A pharyngostomy is most often performed in order to place a feeding tube. This is indicated if the patient is anorectic, or if it is necessary to bypass the oral cavity, the esophagus and/or the crop. The patient is placed in left lateral recumbency and the right side of the neck is surgically prepped from the caudal aspect of the mandible to the midcervical region. A small incision is made through the skin and the underlying esophagus is identified. A moistened cotton-tipped applicator or mosquito hemostat is inserted through the mouth and pharyngeal region and visualized through the skin. A small 1- to 2-mm incision is made over this swab in an avascular area. The tube is grasped with the ends of the mosquito hemostat to facilitate entry into the crop and advanced through the lower esophageal sphincter to the proventriculus, depending on the location of the pathology or disease condition that necessitated placement of the feeding tube. The external end of the tube is then sutured in place with two simple interrupted sutures, incorporating the skin and esophageal crop wall on both sides of the incision. The area is bandaged to protect the site, directing the external portion of the tube dorsally to prevent it being chewed or manipulated by the patient. When no longer needed, the sutures are cut and the tube removed. The esophagus/crop and skin can be left to heal by second intention.^{1,9} A step-by-step pharyngostomy is shown in (Fig 35.19a-g); the procedural details are similar to those used in other species.

ESOPHAGEAL PERFORATION

Esophageal perforation may be caused by the use of a firm feeding tube, struggling of the patient during tubefeeding, enthusiastic feeding response while a feeding tube is inserted into the crop, or thermal burns followed by necrosis with or without fistulation. Food may enter the subcutaneous space through the lacerated or necrotic esophagus. Severe edema, infection, sepsis, toxemia and necrosis may result. Rapid emergency and supportive care must be instituted. Surgical repair will vary according to the extent of tissue damage, necrosis and infection (see Chapter 14, Evaluating and Treating the Gastrointestinal System, Figs 14.12a-f). The patient is placed in dorsal or lateral recumbency, depending on the location of the tissue damage, and repositioning may be necessary to gain access to all affected areas. A skin incision is made through the overlying skin with a blade, monopolar or bipolar radiosurgery, or with a laser. The subcutaneous and underlying esophagus is then examined to determine the extent of disease. If affected tissues appear healthy, immediate debridement, irrigation and closure may be possible. However, often these patients are diagnosed days to weeks after the initial perforation occurred and severe necrosis and infection are present. These patients may require multiple debridements and irrigation procedures. The external affected area should be bandaged with hydrophilic dressing to promote tissue granulation. Final surgical closure must be delayed until the necrotic tissue has been delineated and resected. Once this is achieved, the esophagus may be closed in a simple continuous inverting pattern, and the subcutaneous and skin closure is routine. A pharyngostomy tube may be placed extending through the lower esophageal sphincter to bypass the esophagus during feeding until the esophagus is healed.1,9

CROP BURN REPAIR

Thermal crop damage with or without fistula formation may occur when overheated juvenile feeding formula is stored within the crop immediately after feeding. These thermal burns may range from minor and inapparent to severe and life threatening. The extent of tissue injury and necrosis may not be evident for several days to weeks. An attempt at immediate surgical repair may fail due to progressive tissue necrosis. With severe or extensive crop burns, the patient is often both septic and toxic.

Fig 35.17a | A macaw with severe oral papillomatosis. The choanal slit is occluded with hypertrophic tissue, as is the majority of the oropharynx.

Fig 35.17c | Silver nitrate can be used to debulk oral papillomas, but care must be taken not to cause chemical damage to adjacent structures within the oral cavity.

Fig 35.18b | Cloacal papillomas may be visualized by applying gentle pressure to either side of the vent. Insertion of lubricated cotton-tipped applications may aid in eversion of the cloacal mucosa and allow visualization of the prominent papillomatous tissue. Papillomas are identified by a characteristic "cobblestone" appearance of the mucosa.

Fig 35.17b | A loupe-monopolar radiosurgical tip can be used to debulk oral masses. Care must be taken not to damage adjacent tissues.

Fig 35.18a | Papillomas may be found on the mucosal surface of the cloaca, oropharynx, esophagus/crop, proventriculus, ventriculus, bile ducts and pancreatic ducts. Cystic regression and recurrence is extremely common, and E. coli and Clostridium spp. are often isolated from the cloaca of affected birds. Surgical resection is recommended, particularly if the mass is causing straining to defecate, secondary cloacal infection, fecoliths, hematochezia, and cloacal prolapse.

Fig 35.18c | Methods for removal of cloacal papillomas include silver nitrate cauterization, cryosurgery, radiocautery, laser surgery, and blade excision. The mass and affected cloacal wall may be everted manually and the mass debulked with any of these methods. If silver nitrate is used, as in this photo, the area must be thoroughly flushed with saline to prevent cauterization of normal mucosa as soon as sufficient tissue has been cauterized to debulk the mass.

Pharyngostomy – step by step Figs 35.19a-g

Fig 35.19a | The length of the tube to be used is determined by measuring from the crop to the level of the

Fig 35.19c | The crop tissue is exteriorized and incised just enough to allow tube insertion.

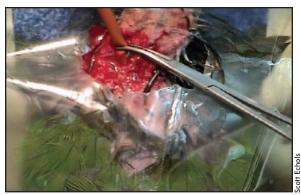

Fig 35.19e | The tube is positioned for suturing.

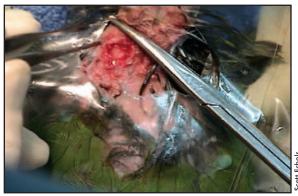

Fig 35.19b | The skin over the crop is incised.

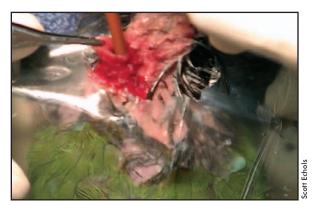

Fig 35.19d | The tube is placed in the crop and slowly advanced toward the thoracic inlet just ventral to the trachea. The surgeon's index finger guides the tube within the esophagus, using the trachea as a guide, advancing into the thoracic esophagus and proventriculus.

Fig 35.19f | A purse-string suture is placed around the tube to prevent crop contents from leaking.

Fig 35.19g | The tube is coiled alongside the head. A bandage is applied that allows syringe access, but prevents the bird from pulling or scratching out the tube.

Despite aggressive medical therapy, some of the patients will succumb within the first hours to days following presentation. Patients in this condition are not surgical candidates. Therefore, topical treatment, hydrophilic bandaging and supportive care are indicated. If a fistula occurs prior to delineation of the affected area and the establishment of a granulation bed, it is important to initiate supportive care. A pharyngostomy tube must be placed if the fistula is large enough as not to allow any appreciable food storage or if weight loss is documented. Otherwise the bandage covering the region may assist in containing the formula.^{1,9} Medical treatment alone may resolve less severe burns, with shrinkage of the scar tissue closing the potential deficit. When the fistulated area has begun to granulate, then surgical repair should be performed.1,9

The patient is anesthetized and placed in dorsal or lateral recumbency, depending on the location of the fistula. The area and surrounding skin are prepared aseptically. Do not use alcohol, as it may gain access to the esophagus and damage the serosa. A circumferential incision is made around the edges of the fistula and the adhered skin is separated from the ingluvies by blunt dissection. Care should be taken not to extend the fistula more than is necessary for removal of necrotic tissue. Placement of a tube or swab into the esophagus from the oral cavity will aid in the delineation of the crop. It is important to note that the skin is normally attached to the crop by two layers of striated muscle that form a sling-like support for the diverticulum of the crop. Once the crop is separated from the skin, the crop is closed in a simple continuous inverting pattern and the overlying skin closed in a simple continuous pattern. The skin and crop should be closed in two separate layers, as there is an increased risk of dehiscence if the two layers are closed together (Figs 35.20a-e).1,9

Occasionally thermal burns are so severe that very little viable tissue remains. The length of the crop should be maintained if possible. Esophageal strictures are more likely to develop if resection and anastomosis are performed than if only a thin strip of esophageal tissue is preserved and allowed to granulate over a stent. If enough viable tissue is present, it may be sutured over a pharyngostomy tube. A longitudinal incision with a transverse closure will increase the diameter of the esophagus and may reduce the risk of esophageal stenosis. The patient must receive frequent small feedings of a soft or liquid diet until the crop stretches and the holding capacity increases. If there is not enough viable esophageal tissue present to close the defect, it may be allowed to heal by second intention while a pharyngostomy tube is in place. Alternatively, a dermoplasty may be performed once healthy granulation tissue is present.

A rotating skin flap will usually cover the defect. 1,9

INGLUVIOTOMY AND CROP BIOPSY

Pet birds, particularly neonates, are susceptible to ingestion of foreign materials. Feeding tubes, substrate and small toys are commonly ingested. The foreign materials will obstruct food passage and irritate the crop. Small objects may be retrieved from the crop by esophagoscopy or by manual retropulsion and withdrawal with a hemostat or tissue forceps. Manual retropulsion is noninvasive, but may result in inadvertent concurrent retropulsion and subsequent aspiration of liquid from the crop. Care must be taken not to damage the crop, esophagus, pharynx, oral cavity and choana, and a thorough examination of all structures should be performed after retrieving the object to note any trauma or remaining pieces of material. An endoscopic exam of the oral cavity, choana, pharynx, esophagus and crop after removal of foreign substance is useful to determine if there is any damage to these structures. 1,9

Indications for an ingluviotomy include foreign body retrieval, endoscopic access to the proventriculus and ventriculus, or biopsy of the crop for histopathologic evaluation. The patient is placed in dorsal recumbency and skin prepped routinely. It is important that the patient be intubated and, if there are contents within the crop, it is recommended to occlude the upper esophagus with a moistened gauze sponge to prevent any refluxed ingesta from entering the airway. An incision is made through the skin over the left lateral portion of the crop. This may be performed by scalpel, monopolar or bipolar radiosurgery, or with a laser unit. The skin is bluntly dissected to identify the crop. Stay sutures are placed in the crop wall to assist in manipulation of the crop, facilitate incising the crop and to prevent uncontrolled exit of material within the crop. The crop is then incised at the cranial aspect of the left lateral side of the sac. This area of the crop is less prone to stress as the crop fills and is not within the path of a feeding tube should the patient require tube-feeding postoperatively. This crop incision should be made with a scalpel blade or sharp scissors to preserve the integrity of small blood vessels. Radiosurgery should be used only to coagulate vessels. If the ingluviotomy is being performed for foreign body retrieval or for access to the proventriculus and ventriculus for an endoscopic exam, the incision into the crop should be performed in a relatively avascular region to control hemorrhage. If the purpose is to collect a biopsy of the crop for histopathologic examination—such as those performed as part of a diagnostic workup in patients demonstrating clinical signs consistent with proventricular dilatation disease—this biopsy should be collected from a vascular region, as it is crucial

Crop Burn Repair - Step by Step Figs 35.20a-e

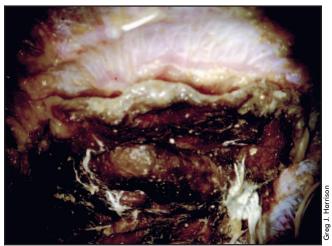

Fig 35.20a | A severe crop burn that has been allowed several days to granulate. With the initial edema gone, the tissue layers can be more easily identified and separated for repair (6x).

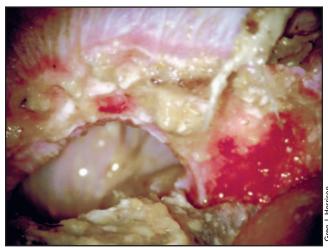

Fig 35.20b | The necrotic skin and the anterior wall of the crop have been removed in the scab (6x).

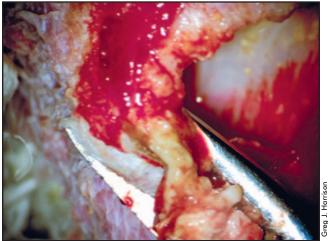

Fig 35.20c | Scissors are used to cut the granulated union of the skin and the crop into separate layers (6x).

Fig 35.20d | Trimming of devitalized or granulated tissue (6x).

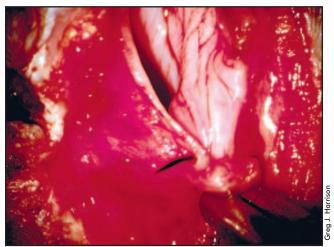

Fig 35.20e | A simple interrupted inverting suture pattern is used to close the crop (6x).

to collect nerve tissue that typically can be found in close proximity to blood vessels. Closure of the crop is accomplished with a simple continuous pattern oversewn with an inverting pattern with an absorbable monofilament suture on an atraumatic needle. Skin closure is routine (Figs 35.21a-h).^{22,25,57}

ESOPHAGEAL STRICTURE CORRECTION

Esophageal strictures may develop as a result of previous infection (trichomoniasis, capillariasis, candidiasis), trauma from tube-feeding, thermal or caustic burns, ingestion of a foreign body or secondary to iatrogenic surgical trauma. Therefore, once an esophageal stricture is diagnosed, the underlying etiology must be determined and addressed. It may be necessary to place a pharyngostomy tube for alimentation. The stricture may be resolved by passing a series of tubes of increasing diameter through the oral cavity and esophagus past the stricture over a period of several weeks.²⁵

CELIOTOMY

There are several surgical approaches to the avian coelom. These include the left lateral, right lateral, ventral midline, and cranial, mid and caudal transverse approaches. Skin incisions vary with the surgical procedure and amount of coelomic exposure required. The surgeon should evaluate the skin and subcutaneous tissues overlying the surgical site for any sign of trauma, fatty infiltration, infection and necrosis. The surgical approach should maximize exposure of the coelomic organs, but minimize the involvement of diseased skin and subcutaneous tissues. For any celiotomy, the cranial part of the patient should be elevated between 30 to 40° to prevent fluids used for irrigation, or coelomic fluid,

from flowing craniad and entering the respiratory tract following penetration of the air sacs. If coelomic fluid is present, as much should be aspirated as possible or surgery delayed until the fluid is resorbed. If coelomic fluid is aspirated while the patient is anesthetized, it may be necessary to adjust the vaporizer setting as the air sacs are allowed to completely expand and anesthetic gas concentration increases.^{1,9}

The left lateral celiotomy provides the best exposure to the proventriculus, ventriculus, female reproductive tract, left testicle, spleen, left kidney and the left ureter. The patient is placed in right lateral recumbency and the site surgically prepped. The caudodorsal border of the sternum is palpated, and the pelvic bones including the cranial pubis are identified. The left leg may be retracted caudally, creating a fold from the knee to the lateral margin of the sternum (knee web) to increase exposure to the cranial coelom (Figs 35.22a-h). Alternatively, the leg may be retracted cranially to increase surgical exposure to the caudal coelom (Figs 35.22i-p). Lung tissue can be visualized percutaneously between the fifth through seventh ribs in smaller birds. The latissimus dorsi and iliotibialis cranialis muscles obscure visualization of lung tissue in larger species. The skin is incised using monopolar or bipolar radiosurgery or with a laser from the cranial to caudal left paralumbar region. At the cranial edge of the knee web, just caudal to the last rib, the incision is continued caudoventrally to pass through the groove of the groin web to the region of the pubic bone. Once the skin incision is complete, the left leg may be further retracted caudodorsally to expose the abdominal wall. A branch of the superficial medial femoral artery and vein, visible passing over the lumbar fossa toward the pubis, should be cauterized. The abdominal wall incision is initiated in the external abdominal oblique

Ingluviotomy - Step by Step Fig 35.21a-h

muscle, just caudal to the last rib. This incision is extended caudally through the internal abdominal oblique and *transverses abdominis* muscles to the cranial aspect of the pubis.^{1,9,25,78}

In order to achieve adequate exposure to the cranial coelom, the last one to two ribs may be transected. The intercostal blood vessels course along the cranial edge of each rib and require ligation or coagulation. In small birds, these vessels may be coagulated by inserting the indifferent electrode of the bipolar radiosurgical forceps inside the thoracic wall, lightly apposing the electrodes at the cranial edge of the rib and then activating the electrodes. In larger species, it is recommended to clamp these vessel cranial to the ribs, transect the ribs and then apply a hemostatic clip to the respective vessel. Occasionally it is necessary, particularly in larger birds, to transect the last two ribs dorsally and ventrally and remove this section of the rib entirely. 19,25,42

Retraction of the abdominal wall may be maintained by a Heiss, Alm, mini-Balfour or Lone Star retractor. Retraction in smaller patients such as budgerigars may be achieved by gently applying a Halstead or Hartman mosquito forceps to the skin flap. This will avoid hemorrhage that may occur with retractors that penetrate tissue. Alternatively, ophthalmic lid retractors may be used. As the caudal thoracic air sac is entered, the caudal aspect of the lung is visible, including the ostium of the bronchi entering the abdominal air sac. The liver is noted ventrally and the proventriculus dorsally. If the abdominal air sac is entered, the lung will lie dorsolaterally. The intestines are apparent and may be gently manipulated with a moistened cotton-tipped applicator, ring-tipped ophthalmic forceps or microvascular surgical forceps. Toothed forceps traumatize intestinal tissue and may cause perforation. The proventriculus is located medially and is suspended by air sacs and suspensory ligaments. The intestines may be retracted caudally and ventrally to reveal the left kidney located dorsomedially in the coelom. The ovary or left testicle is visible at the cranial edge of the kidney and the adrenal gland noted between the gonad and the cranial division of the kidney. Obesity and organomegaly may alter anatomic location and obscure visualization of certain organs. 1,9,42

Transected ribs are not surgically reattached during closure, but left in the correct anatomic location surrounded by soft tissues. If the seventh and eighth ribs have been removed, tension-relieving sutures must be placed from the abdominal musculature to the sixth rib. The abdominal musculature is closed with absorbable monofilament suture in a simple interrupted or continuous pattern. Skin closure is routine. 1,9

A ventral midline, transverse or combination approach

to celiotomy provides surgical access to the middle and both sides of the coelomic cavity. These approaches provide access to the small intestine, pancreas, liver, testes, oviduct (when enlarged) and cloaca.^{1,9,24}

The patient is positioned in dorsal recumbency and the site surgically prepared. Most avian species have a relatively large superficial vein located subcutaneously on the ventral abdomen. This vein may be coagulated prior to incising the abdominal wall to prevent hemorrhage. The skin is incised on the ventral midline from the caudal sternum to the interpubic space. The linea alba is identified and tented upward midway between the caudal sternum and interpubic space. It is then carefully incised with bipolar radiosurgical forceps, and the surgeon may inspect the underlying tissue for adhesions or other attachments to the peritoneum. If adhesions to the abdominal wall are noted or strongly suspected, the coelomic cavity may be evaluated with the use of an endoscope prior to extending the incision. These adhesions may be broken down with the use of a cottontipped applicator or other blunt instrument. If adhesions cannot be broken down, an alternative surgical approach may be necessary. The incision is extended cranially and caudally by inserting the indifferent electrode under the linea alba, apposing the tips with the linea in between them and initiating the current while dragging the forceps cranially and caudally. This will incise the abdominal wall while preventing any hemorrhage. Extreme caution must be practiced not to extend this incision too deeply to prevent iatrogenic trauma and laceration to the duodenum and pancreas, which lie from left to right just inside the abdominal wall. 1,9,24

A transverse and ventral combination celiotomy may be performed to increase exposure to the coelomic cavity. An incision may be performed in the cranial region (5-7 mm from the caudal border of the sternum), midabdomen or caudal region (5-7 mm from the cranial border of the pubic region). Care must be taken when making a caudal transverse incision, as intestinal loops often lie just under and may be attached to the abdominal musculature. A transverse incision is performed on one or both lateral sides caudal to the sternum, leaving sufficient tissue caudal to the sternum to allow subsequent closure. The size of the incision should be large enough to provide adequate exposure, but small enough to minimize escape of anesthetic gas and minimize hypothermia. Please refer to Chapter 33, Updates in Anesthesia and Monitoring for a discussion regarding anesthetic considerations for the avian patient during a celiotomy. The abdominal wall is closed using a simple continuous or interrupted pattern with an absorbable monofilament suture. Skin closure is routine. 1,25,57

Proventriculotomy and Ventriculotomy

Proventriculotomy is indicated for the removal of foreign or toxic material from the proventriculus or ventriculus if endoscopic retrieval is unsuccessful or impossible. 1,9,42,78 The patient is positioned in right lateral recumbency. A left lateral celiotomy is performed to provide the best exposure to the proventriculus and ventriculus. The ventral suspensory structures must be dissected bluntly to retract the proventriculus caudally. Stay sutures are placed in the wall of the ventriculus to exteriorize and manipulate both structures. The proventriculus is fragile and may tear or bruise if manipulated with toothed forceps or if stay sutures are placed in this organ. Certain atraumatic microsurgical instruments may be used to manipulate the proventriculus. The coelomic cavity should be packed with moist gauze sponges to prevent gastric contents from leaking into the coelom and assist in minimizing escape of anesthetic gas. 1,9,42

The proventriculotomy is initiated at the isthmus (junction of the proventriculus and ventriculus) with scissors. This incision is extended into the body of the proventriculus. Hemorrhage from the cut surface of the proventriculus is controlled by radiocautery. Proventricular contents and foreign material may be removed by suction or with a small curette. The lumen should be well irrigated after foreign body removal, and an endoscope may be used to perform an examination of the proventriculus prior to closure to ensure that all material has been successfully removed. The proventriculus is closed using a simple continuous pattern oversewn with a continuous inverting pattern using a fine, absorbable monofilament suture with an atraumatic needle. The inverting pattern should extend beyond the incision on both ends and the integrity of the closure evaluated with the injection of sterile saline. Abdominal wall and skin closure are routine.1,9,42

Postoperative fasting is not necessary and the patient should be offered food and water once completely recovered. The strength of the incision is strongest immediately postoperatively and during the fibroblastic stage. Leakage of gastric contents is not an infrequent occurrence due to the lack of omentum in birds. If the proventricular wall appears thin or friable, it may be necessary to place a duodenal feeding tube for temporary alimentation. This will allow enteral alimentation of the patient while bypassing the proventricular incision during healing (Figs 35.23a-k).^{1,9,42}

The ventriculus may be accessed either through a proventriculotomy incision or through the ventriculus itself. The ventriculus is extremely vascular with heavy musculature in psittacine species, and healing postoperatively can be prolonged. Therefore, access to the ven-

triculus through the previously described proventricular incision is preferred when possible. The incision is initiated at the isthmus and extended into the ventriculus. The entrance into the ventriculus may be gently dilated to insert instruments to remove any foreign material, apply suction and irrigate the lumen. The ventriculus may be assessed with an endoscope to ensure complete removal of any foreign material.

An alternate approach to the ventriculus is through a cranial transverse celiotomy just caudal to the sternum. The ventriculus is identified and gently rotated clockwise to expose the thinnest portion of the ventricular wall. A longitudinal incision is performed with monopolar radiosurgery through the ventricular wall to access the luminal contents. The incision is typically 1 cm in length in a 400-g bird. Material may be removed with an appropriately sized spatula or curette. Foreign material may be removed from the proventriculus as well. The incision is closed using a horizontal mattress pattern with a slowly absorbable or non-absorbable monofilament suture. Care should be taken that the ventricular lumen is not penetrated during closure. 19,42

The serosal surface of the proventriculus or ventriculus also may be biopsied when evaluating a patient for proventricular dilatation disease. It is important to biopsy a vascular region to ensure that the surgeon has obtained nervous tissue. Abdominal wall and skin closure are routine. 1,9,42

Intestinal Resection/Repair/Anastomosis Surgery

Intestinal surgery may be indicated in the following presentations:

- 1. Obstructions, either from foreign bodies or secondary to adhesions or scarring.
- 2. Intestinal neoplasia.
- 3. Undiagnosed intestinal disease requiring biopsy.
- 4. Traumatic incidents, often involving bite wounds from predator species.
- 5. Congenital herniation and strangulation.
- 6. Repair of iatrogenic damage to the intestine occurring during celiotomy.

The patient is placed in dorsal recumbency and a midline or transverse celiotomy is performed. The vascular supply to the small intestine is via the celiac artery to the duodenum and the cranial mesenteric artery to the jejunum and ileum. Any necrotic bowel is resected gently using microsurgical instruments to prevent damage to healthy intestinal tissue. An anastomosis is performed using a 6-0 to 10-0 absorbable monofilament suture on a one-fourth-circle atraumatic needle. Typically six to eight simple interrupted sutures are necessary for end-to-end anastomosis. Abdominal wall and skin closure are routine. 19,25,42

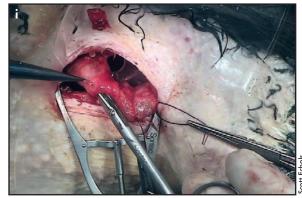

Fig 35.23h-i | Access to the lumen of the proventriculus and removal of contents and metal object noted on radio-araph.

Fig 35.23k | Proventricular closure.

Enteral feeding tubes may be placed in the duodenum. This is indicated if it is necessary to bypass a diseased portion of the alimentary system. The patient is placed in dorsal recumbency and a midline or transverse celiotomy is performed. An indwelling jugular catheter, no less than one-third the diameter of the small intestine, is placed through the left abdominal wall and into the descending duodenal loop. The catheter is then advanced gently through the descending and ascending duodenal loops and the needle withdrawn from the intestine and abdominal wall. One to two sutures are placed with 5-0 monofilament in the intestine and abdominal wall to secure the intestine to the body wall and provide a tight seal. The patency and seal of the catheter is tested by injecting sterile saline solution and the celiotomy is closed routinely. The external portion of the catheter is secured using monofilament suture. The excess catheter is coiled and secured to the patient anterior to the leg and under the wing. An appropriate type and amount of a liquid diet is used to aliment the patient. 1,9,25,42 Hyperosmotic diets may cause an osmotic diarrhea. The amount to be fed should be divided into equal volumes and injected 4 to 6 times daily at a rate of approximately 1 ml/15 seconds to allow the intestine to accommodate for the volume. The catheter should be flushed with warm water or lactated Ringer's solution before and after injecting the food to prevent obstruction of the catheter.1,9

The patient and surgical site must be monitored closely for leakage and coelomitis, and for damage to the catheter and/or the incision site. Once the catheter is no longer needed, the suture is cut, the catheter removed and the incision is left to heal by second intention.^{1,9,25}

Surgery of the Reproductive Tract

ANATOMY OF THE FEMALE REPRODUCTIVE TRACT

The avian oviduct is divided into five anatomic regions, which are microscopically distinguishable (see Chapter 18, Evaluating and Treating the Reproductive System).

The avian oviduct is suspended via the dorsal and ventral ligaments within the coelomic cavity. The cranial, middle and caudal oviductal arteries run through the dorsal mesentery vascular supply to the oviduct. Species variations exist, but in general the cranial oviductal artery arises from the left cranial renal artery, aorta or external iliac artery. The middle oviductal artery arises from the left internal iliac artery or the pudendal artery. Venous blood from the cranial oviduct enters into the caudal vena cava via the common iliac vein and venous blood from the caudal oviduct enters the renal portal or

hepatic system^{24,43,45,59} (see Chapter 7, Emergency and Critical Care Fig 7.16-7.19).

OVOCENTESIS AND MANUAL EGG DELIVERY

Egg binding and dystocia occur in many pet bird species. If medical therapy fails to deliver the egg, ovocentesis or manual delivery may be attempted prior to a celiotomy. The clinician should be prepared to perform a celiotomy when attempting ovocentesis or manual delivery, as retropulsion of the egg and oviductal rupture, resulting in an ectopic egg, shell fragments or yolk coelomitis, are potential complications. A celiotomy with or without salpingohysterectomy may, in some cases, be a more rapid and effective method of resolving dystocia (see Chapter 7, Emergency and Critical Care Fig 7.16-7.19).

SALPINGOHYSTERECTOMY

Salpingohysterectomy involves removal of the oviduct. Salpingohysterectomy is indicated to prevent egg production, resolve disease conditions associated with egg production, infectious/inflammatory disease of the oviduct, oviductal neoplasia, oviductal torsion, oviductal prolapse, and weakening or herniation of the abdominal wall secondary to chronic reproductive activity.^{3,9,24,34,51,76} It is not typically performed as a preventive procedure due to possible risks, namely hemorrhage, to the patient during the procedure. However, techniques such as endoscopic salpingohysterectomy in juvenile cockatiels have been described as preventive procedures for removal of the oviduct in juvenile birds.72 During sexual and egg-laying activities, the oviduct is hypertrophied and blood supply to the ovary and oviduct is significant. It is recommended to delay surgery if possible until the reproductive tract is in an inactive state, thereby reducing the risk of hemorrhage to the patient. Egg production may be stopped, and ovarian and oviductal size and vascularity may be reduced by medical therapy prior to surgery. Please refer to Chapter 18, Evaluating and Treating the Reproductive System for a complete description of medical therapy to reduce egg production. 1,9,24

The size and condition of the oviduct varies with the reproductive and physiologic state of the patient. Birds suffering from previous reproductive disease, particularly coelomitis, may have significant adhesions, which complicate surgical removal of the oviduct. These may include adhesions between the oviduct and the kidney, the cloaca and other coelomic structures. Caution must be taken when separating these adhesions, as hemorrhage and tearing of the affected tissue may occur. A hormonal feedback loop presumably exists between the uterus and the ovary to control follicular development and ovulation. In many birds following salpingohysterectomy, follicles will develop but will not progress to ovulation. However, some birds, namely Anseriformes, will develop large follicles and ovulate freely into the coelom. These ova may be resorbed without incident, but some birds will develop coelomitis. Clients should be informed of this potential and medical therapy to control ovulation, ovariectomy or cryosurgery of the ovary may be considered in these patients. 9,24,43

For salpingohysterectomy, the patient may be placed in right lateral recumbency and a left lateral celiotomy is performed. Alternatively, the patient may be placed in dorsal recumbency and a ventral midline celiotomy with or without a midabdominal transverse incision may be performed. 9,24,49 The ovary is visible at the cranial pole of the left kidney, adjacent to the adrenal gland. It may be necessary to retract the proventriculus and ventriculus ventrolaterally to improve exposure of the oviduct. The convoluted oviduct lies along the dorsal body wall in proximity to the caudal vena cava. The ventral ligament, responsible for these oviductal convolutions, courses caudally and becomes a muscular cord at the vagina. This ligament is dissected with bipolar radiosurgery to allow the oviduct to be released and positioned in a linear fashion. 1,9,76

The fimbria of the funnel portion of the infundibulum lies caudal to the ovary and is elevated to expose the dorsal attachments. The dorsal ligament that suspends the uterus and a branch of the ovarian artery course(s) caudally along the uterus from the base of the infundibulum. A small blood vessel is identified from the ovary through the infundibulum and is coagulated and transected with bipolar radiosurgical forceps or ligated with a hemostatic clip. If it is accidentally transected without coagulation, it retracts dorsal to the ovary and is irretrievable. Manual pressure and application of a small piece of absorbent gelatin sponge or beaded polysaccharide powder may be used to achieve hemostasis. The remaining suspensory tissue may be dissected with bipolar radiosurgical forceps. 1,9,24

The oviduct is retracted ventrocaudally once the infundibulum is free. This exposes the dorsal suspensory ligament, several small blood vessels and branches of the ovarian artery, which should be coagulated or ligated with hemostatic clips. As the dissection is continued caudally toward the cloaca, the ureter is identified as a white, tubular structure extending from the kidney to the cloaca. The ureter courses along the terminal colon and enters the cloaca, and should be identified and avoided. The uterus is ligated at its junction with the cloaca with hemostatic clips, using caution not to trap the left ureter (Figs 35.24a-j).1,9,24

Alternatively, if the oviduct does not contain any infectious material, two hemostatic clips may be placed at the mid-magnum region and the tissue between them transected. This results in the removal of two shorter sections. The cranial portion is retracted ventrally and bipolar radiosurgical forceps are used to coagulate vessels and transect the oviductal ligament, thereby freeing the cranial oviductal section from the dorsal body wall and facilitating its removal. Once the cranial portion is removed, the caudal portion is retracted ventrally and bipolar radiosurgical forceps are used to coagulate vessels and transect the oviductal attachments caudally toward the cloaca. The ureter is identified and avoided. A hemostatic clip or ligature is applied at the junction of the uterus and cloaca, avoiding the ureter, and the uterus is transected with radiosurgical forceps or scissors and removed. It is important to ligate the entire circumference of the uterus to prevent any postoperative reflux and leakage of feces and urates from the cloaca into the coelom. Closure is routine and previously described. Samples are collected for cytology, bacterial culture and histopathologic examination, when indicated. 1,9,24

CAESAREAN SECTION/OVIDUCTAL-SPARING CELIOTOMY

It is often recommended that a salpingohysterectomy be performed when a celiotomy is necessary for reproductive problems such as removal of an egg that is bound. However, it may be necessary to salvage the reproductive capabilities of some avian patients. In addition, it may be prudent in some patients to initially remove the problematic egg without performing a hysterectomy, employ medical therapy to reduce the size and vascularity of the oviduct, and perform a salpingohysterectomy at a later time. The surgical approach varies with the location of the egg. If located cranially, a left lateral celiotomy is recommended, and if caudally located, a ventral midline approach with or without a transverse incision provides optimal exposure. The oviduct is incised directly over the egg, avoiding obvious blood vessels, and the egg removed. The oviduct is examined for gross abnormalities and samples are collected for cytology, bacterial culture and histopathologic examination. The oviduct is closed with a simple interrupted or continuous pattern using an absorbable monofilament suture. An inverting pattern is not recommended since this may reduce the oviductal luminal diameter. Abdominal and skin closure are routine. It is recommended to rest the hen from reproductive stimuli for a minimum of 2 to 4 weeks and if possible for the remainder of the reproductive season or longer, based on culture and histopathologic results. It is crucial to identify and correct the etiology that initiated dystocia prior to resuming breeding.24

REMOVAL OF THE OVARY AND OVARIAN BIOPSY

Partial or complete ovariectomy may be indicated in patients that suffer from ovarian neoplasia, ovarian granulomas, persistent follicular activity, oophoritis and ovarian cysts that do not resolve with medical therapy. It is a challenging procedure and often poses great risk to the patient. Due to this risk, medical alternatives including hormonal manipulation and intralesional chemotherapeutic administration should be explored. It also is important to note that none of these procedures have been satisfactorily studied in pet birds. Laparoscopic ovarian biopsy is generally preferred. Hemorrhage is a significant potential complication and the clinician should be prepared to perform an emergency celiotomy during the laparoscopic procedure. 1.24,57

The avian ovary is attached to the cranial kidney and the dorsal body wall by the mesovarian ligament and receives its blood supply from the ovarian artery, which originates from the left cranial renal artery or directly from the aorta. Accessory ovarian arteries also may arise from adjacent arteries. The ovarian artery further divides into many branches, with the greatest blood flow directed to any large preovulatory follicles that are present. Ovarian veins join to form the main anterior and posterior veins that drain into the overlying vena cava. Multiple left ovarian veins may be present and drain into the cranial oviductal vein. Venous blood then enters the common iliac vein and finally the vena cava. The cranial oviductal vein may be too short or too poorly developed to identify. Multiple short veins appear to enter the common iliac vein over the length the dorsal base of the ovary. 24,34,43,45,59

The ovary is tightly adhered to its dorsal attachments. This makes complete excision of the ovary extremely difficult and poses significant risk of hemorrhage to the patient. The avian ovary is attached to the cranial renal artery by a short stalk and the attachment to the common iliac vein is intimate and extensive. Life-threatening hemorrhage often occurs from a lacerated common iliac vein during ovariectomy.²⁴

Ovariectomy and salpingohysterectomy may be attempted in the juvenile bird as an effort to prevent future reproductive disease. Ovariectomy has been described in many poultry studies. Unfortunately, most articles poorly elucidate the exact technique or associated complications. 52,66,70,81,86 Any of these procedures still pose significant risk to the hen, and clients should be well counseled regarding the potential for hemorrhage and complications. A ball-tipped electrocautery probe may be used to coagulate ovarian follicles of immature hens. However, this procedure results in ovarian regeneration

Salpingohysterectomy via Left Lateral Celiotomy – Step by Step Figs 35.24a-j

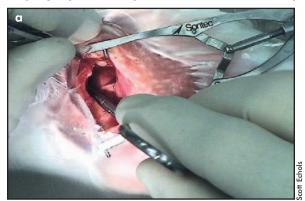

Fig 35.24a | From the left lateral approach with the leg caudal, the bird will undergo a salpingohysterectomy.

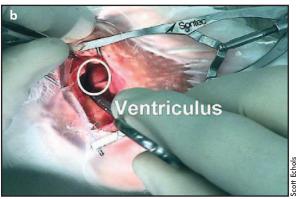

Fig 35.24b | Opening the confluent wall of the air sacs and the suspensory tissues of the proventriculus to allow entry into the hepatoperitoneal cavity.

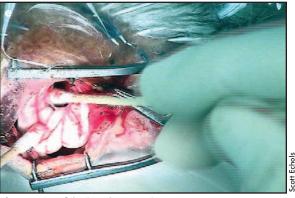

Fig 35.24c-f | Identifying and exteriorizing uterine tissues for a salpingohysterectomy and/or ovary removal. The use of cotton-tipped applicators allows the very fragile uterus to be manipulated. The blood supply comes from the dorsal aspect of the salpinx and uterus, or from vessels via the ovarian or cloacal areas. Exteriorizing the body of the uterus and transecting it, allows the maximum visualization of the vessels and surrounding tissue that must not be traumatized. Bisecting a large uterus as shown in the lower example can simplify exteriorization.

in mature hens. A procedure to remove the ovary of juvenile hens includes manually removing the ovary in toto. The caudal end of the ovary is grasped with angled hemostats and pulled gently in a cranial direction with clear separation from the dorsally located common iliac vein. When performing this procedure it is important to stop immediately if any resistance occurs to prevent tearing of the overlying vein.9,24

Ovariectomy in the adult hen must include removing

ovarian follicles or cysts, debulking the mass of the ovary and then removing the ovary just ventral to its blood supply. The patient is placed in right lateral recumbency and a left lateral celiotomy is performed. Any large preovulatory follicles are either manually debulked or aspirated. Blood-filled follicles may represent previously ruptured blood vessels from an invasive mass and caution must be taken when removing these to prevent hemorrhage. Ovarian cysts should be aspirated. When aspirating

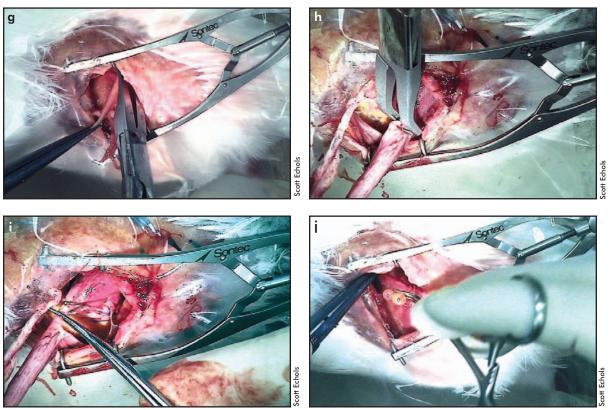

Fig 35.24g-i | Hemostatic clips are applied to the portion of the uterus that attaches to the cloaca. The uterus can then be transected and removed. The anterior vessels from the uterine ligament are ligated with hemoclips in a similar manner (Sealing these vessels with radio current alone is not sufficient). If hemostasis is not achieved in a rapid and thorough manner, the accurate placement of oxidized regenerated cellulose mesh may be required. Closure is routine. Some birds (especially budgies) have very thin paralumbar musculature and sutures tend to tear easily. Including the medial tissues of the thigh and encircling a rib with suture and then a layer of the cellulose mesh to fill the deficit has worked in such cases. Topical and systemic analgesics are needed.

follicles or cysts, a small (23-25 gauge) butterfly catheter may be inserted into the most avascular region to prevent hemorrhage and the contents aspirated. Care must be taken not to spill aspirated contents, particularly in conditions such as oophoritis, which could result in development of infectious coelomitis. Once follicles and/or cysts have been removed or aspirated and collapsed, the ovarian surface is visible and prepared for debulking. Leakage of cystic contents does not typically result in coelomitis in non-infectious conditions.²⁴

An angled DeBakey neonatal vascular clamp is applied dorsal to the ovary to occlude the vascular supply. This clamp is atraumatic, remains in the surgical site without obstructing the surgeon's view and provides hemostasis. This clamp must be applied parallel to the spine to avoid entrapping the aorta and peripheral nerves. The ovarian tissue is excised with the use of a monopolar radiosurgical wire loop until very little tissue protrudes through the hemostatic clamp. The vascular hemostat is carefully opened, but left in place while the area is monitored for hemorrhage. If hemorrhage occurs the hemostat may be replaced. If possible, the vascular clamp is then opened, moved dorsally and reapplied to the ovar-

ian base. This process is continued until the overlying vasculature is clearly visible and the course of the common iliac vein may be seen.²⁴

Once the bulk of the ovary has been removed, the vascular supply must be securely ligated and the remaining ovarian tissue excised. One to two hemostatic clips are applied dorsal to the vascular clamp with 90° clip applicators. It is recommended to apply the first clip in a caudal-cranial direction and the second clip in a cranial-caudal direction to incorporate the entire vascular supply. The remaining ovarian tissue is excised with the use of a monopolar radiosurgical wire loop. Another procedure may be pursued if the ovarian attachment to the common iliac vein is too extensive to apply hemoclips, or if there is erosion into the overlying vessel, as with some invasive ovarian neoplasia. The common iliac vein is ligated with a hemoclip just caudal to the ovary and cranial to its junction with the caudal renal vein. When performed properly, the ovarian artery and common iliac veins are effectively clamped. This allows the surgeon to carefully dissect the ovarian tissue from the overlying vessels. If necessary, the ventral wall of the common iliac vein may be safely removed. It is important to note that

there is a significant risk of damaging the left adrenal gland, significantly altering blood flow through the renal portal system and the cranial renal division, and damaging the overlying kidney and lumbar and/or sacral nerve plexus. Closure is routine and the patient must be monitored for postoperative hemorrhage.9,24

There are reports of carbon dioxide laser ablation and cryosurgical destruction of the ovary and neoplastic tissue (R. Wagner, personal communication, 2003). These techniques may allow for more complete removal of ovarian tissue and less risk of hemorrhage, however, ablation must be strictly controlled to prevent damage to the adrenal gland, vascular supply to the left kidney and local nerves. Removal of avian gonads with laser often resulted in severe hemorrhage intra- and postoperatively.2

ANATOMY OF THE MALE REPRODUCTIVE SYSTEM

The male avian reproductive system includes the testes, the epididymis and the ductus deferens. The testes are located just ventral to the cranial division of the kidneys and are connected to the dorsal body wall by the mesorchium. The epididymis is located at the testicular hilus at the dorsomedial aspect of the testes, and continues caudally lateral to the ureter and terminates at the urodeum as papillae ventral to the ureteral ostium. The testicular artery arises from the cranial renal artery and provides most of the arterial blood supply to the testes. Budgerigars and passerines have a seminal glomus at the distal ductus deferens that forms a prominent projection and serves for sperm storage. There may be an accessory artery that arises directly from the aorta. Venous blood either returns directly to the vena cava or forms a common vessel with the adrenal veins. Testicular vasculature may vary among avian species or individuals. 24,46,48,59

ORCHIDECTOMY AND **TESTICULAR BIOPSY**

Indications for orchidectomy include testicular neoplasia, testicular cysts, and infectious and inflammatory conditions of the testicle(s) that are unresponsive to medical therapy. 1,9,24,30,83 Laparoscopy is the preferred method for testicular biopsy. 15-17

Castration techniques have included simple extraction in chickens (caponization), laser ablation, intravascular suction and complete surgical excision. Testicular regrowth is extremely common unless the entire testicle is completely removed. Removal of testicles carries significant risk of hemorrhage and should not be used in place of behavioral therapy, environmental manipulation, or exogenous hormone therapy for testosterone-related behavioral disease. In addition, castrated Gamble's and scaled quail

maintained ornate breeding plumage and exhibited overt aggression, demonstrating that these behaviors were either learned or resulted from the influence of hormones other than testicular-produced testosterone.^{24,60}

Medical therapy is instituted prior to surgery to reduce the size of active testicles. Several surgical approaches have been described. The patient may be placed in dorsal recumbency and a ventral midline celiotomy with or without a transverse flap is performed. This provides access to both the left and right testicles if both are to be removed. Alternatively, a lateral celiotomy may be performed to gain access to either the left or right testicle. It is possible to access the opposite testicle from a lateral incision by incising the midline junction of the corresponding air sacs.^{9,24}

The testicle is gently retracted ventrally and a 90° vascular hemostat or hemostatic clip is applied to the base of one testicle with 90° clip applicators incorporating its vascular supply. The hemostat or clip must be applied parallel to the spine to avoid entrapping the aorta and peripheral nerves. If possible, a second clip is applied just ventral to the first. One clip is applied in a cranialcaudal direction and the second clip in a caudal-cranial direction to incorporate the entire vascular supply. The base of the testicle is incised between the hemostat or clip and the ventrally applied clips with a scalpel blade, scissors or radiosurgery. Alternatively, the testicular tissue may be debrided with the use of a monopolar radiosurgical wire loop or excised with scissors until very little tissue protrudes through the hemostatic clips. The vascular hemostat is carefully opened, but left in place while the area is monitored for hemorrhage. If hemorrhage occurs the hemostat may be replaced and another hemostatic clip applied dorsal to the previous clips, or if hemorrhage is minor a small piece of hemostatic gelatin sponge or beaded polysaccharide powder may be placed over the area. Any remaining testicular tissue that protrudes through the hemostatic clip may be ablated with electrocautery or a laser. Residual testicular tissue may result in tissue hyperplasia and produce reproductive hormones. Closure is routine and the patient must be monitored for postoperative hemorrhage. 9,24

VASECTOMY

Indications for vasectomy in birds include providing "teaser males" and to control reproduction. This procedure is not typically performed in pet birds. In the budgerigar, the patient is placed in dorsal recumbency and a 3- to 7-mm incision is made lateral to the cloacal sphincter. The fat and abdominal musculature is carefully dissected to enter the coelomic cavity. An operating microscope is used to locate the ductus deferens and a 5-mm section of the ductus deferens is excised. The skin is closed routinely. It is recommended to repeat the procedure on the other side 2 weeks later.^{24,77}

In the finch, a 3-mm incision is made 5 mm lateral to the cloaca with the use of an operating microscope. The fat and abdominal musculature is incised to access the seminal glomera. The ductus deferens is carefully separated from the ureter and one or more sections excised without ligation. The skin is closed routinely.^{11,24}

Vasectomy in larger avian patients is performed via transection of the ductus deferens via lateral or transverse celiotomy or laparoscopy. This procedure has been described in Japanese quail (Coturnix japonica). During a laparoscopic approach, the patient is placed in right or left lateral recumbency and the leg pulled cranially. A laparoscope is inserted at the apex of an inverted V created by the semitendinosus muscle as it passes over the last rib. The testis and ductus deferens are identified and distinguished from the kidney, adrenal gland, ureter and common iliac vein. The proximal ductus deferens is isolated and grasped with biopsy forceps. This section of the ductus deferens is transected and removed through the biopsy sheath. Care must be taken not to damage the ureter and common iliac vein. Closure is routine. The patient is repositioned on the contralateral side and the procedure repeated.24,44

Cloacal Surgery

CLOACAL PROLAPSE REPAIR

Cloacal surgery is indicated in those patients suffering from prolapse of the cloaca for removal of cloacoliths, and for cloacal papilloma debridement. Old World psittacines, particularly cockatoos, may develop intermittent or permanent prolapse of the cloaca. Reduced sphincter tone, chronic masturbation and straining, and chronic bacterial cloacitis have been implicated as causes for this disease. A thorough history and medical evaluation often elicits the cause. Medical therapy may include appropriate antibiotics based on cytology and bacterial culture and sensitivity and counseling clients to create a non-reproductive environment. 1,9,24

If unresponsive to medical therapy, surgical intervention may be necessary to prevent the cloaca from prolapsing. Minor prolapse may be resolved by placing temporary mattress sutures on both sides of the vent or by placing two transverse sutures across the vent. Sutures should not be placed in the vent itself due to potential damage to the innervation. Purse-string suture of the vent is contraindicated due to frequent postoperative cloacal atony. Any procedure involving the surgical fixation of the cloa-

cal wall to the abdominal musculature or ribs will interfere with the normal physiologic movement during voiding and egg laying, and may result in significant discomfort to the patient. 1,9,24

Occasionally, cloacal prolapse is due to or results in atony of the vent sphincter. Narrowing the diameter of the vent or performing a ventplasty may treat this condition. This may be accomplished by one of two procedures. Two triangular-shaped wedges are excised from the superficial surfaces of each side of the vent, without traumatizing the muscular or nervous tissue. This creates a reduction in the vent opening by one-third to one-fourth. Simple interrupted sutures are placed with monofilament nylon through the skin and subcuticular tissues. Another procedure to accomplish reduction of the vent opening includes incising one-half to threefourths of the margin of the circumference of the vent to provide a cut surface for healing. Simple interrupted sutures are placed from one side of the vent to the other to partially close the vent opening, thereby preventing prolapse of the cloaca^{1,9,24} (Figs 35.25a-l).

Current theory attributes cloacal prolapse, in many cases, to behavioral and/or nutritional causes. In the interim, however, surgical reduction of cloacal prolapse may be required. Cloacopexy, following various techniques (see text) tends to be a temporary fix at best, unless underlying causes are addressed.

A percutaneous cloacopexy may be performed. This may offer only a temporary resolution, but it is much less invasive than the more extensive procedures later described. (Ed. Note: With behavioral modification and hormonal manipulation, many practitioners are finding the need for more invasive cloacopexy unnecessary. The percutaneous technique has, in these editors' experience, supplied sufficient support to allow for the institution of medical and environmental therapy).

The patient is placed in dorsal recumbency and the abdomen surgically prepared from the caudal sternum to the pubis. The prolapsed tissue is replaced manually or with a lubricated cotton-tipped applicator or gloved lubricated index finger. The applicator may be left in the cloaca to delineate the location of the ventral cloacal wall, or finger or appropriately sized syringe case may be inserted into the cloaca. Two to three percutaneous sutures are placed using monofilament nylon while the intracloacal object gently holds the ventral cloacal wall against the abdominal wall. This aids in displacing intracoelomic organs so as not to entrap them in between the abdominal and cloacal walls. Potential complications include entrapment or perforation of the ureters, rectum, duodenum and pancreas. This is avoided if the suture placement is restricted to the ventral aspect of

Prolapsed Cloacal Repair - Vent Resection and Reduction - Step by Step Figs 35.25a-l

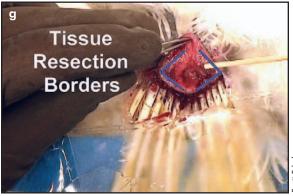

Figs 35.25a-h

Figs 35.25i-l

Figs 35.25a-1 | Prolapsed cloaca is currently considered a malnutritional and/or behavioral disorder. Until corrections for such problems become effective, the prolapses need to be replaced and maintained with some surgical method. Cloacopexy has been used for years, but often proves insufficient for long term treatment. Ventplasty is used to reduce the diameter of the orifice. A thin, superficial dermal layer is removed (c-i) and a routine closure is made. Appropriate space must be maintained to allow passing of droppings but retention of tissues. Over-closing results in retention of droppings. Adjusting the opening in such a case should occur within a matter of hours. Such surgery is often done in cockatoos (notorious self-mutilators) and devices applied to the neck to avoid mutilation are advised, as are pain medicines both systemically and topically.

the body wall, directly lateral to the linea alba. It is important to note that any surgery that places the cloaca in a fixed position will interfere with the dynamic action of the cloaca during defecation and micturition.^{1,9,24}

Birds with chronic cloacal prolapse often have elongated the distal colon from constant straining and subsequent protrusion from the vent. Therefore, although care is taken to remain ventral in the placement of the cloacopexy sutures, this distended colon may be forced to make a "U" turn when the ventral cloaca is sutured too extensively in a cranial direction. This can result in folding of the colon on itself and a functional colonic obstruction. If fecal material is not produced within a reasonable period of time post-cloacopexy, the veterinarian should consider removal of the most cranial abnormal cloacopexy suture.

A circumcostal or rib cloacopexy may be performed in patients suffering from severe cloacal prolapse. The patient is placed in dorsal recumbency and a ventral midline celiotomy is performed. Placing a lubricated cotton-

tipped applicator, gloved finger, or syringe case will facilitate identification and manipulation of the cloaca. The cloacal wall is identified and bluntly dissected from the surrounding fat and subcutaneous tissues. Fat tissue on the ventral surface of the cloaca must be excised for a successful outcome. The ribs are pushed caudally while the abdominal incision is elevated manually. This will bring the ribs into view to facilitate suture placement. An absorbable monofilament suture material is passed around the last rib on the right and left sides. These sutures are then passed through the full thickness of the ventral aspect of the craniolateral extent of the urodeum. Large tissue sections must be used for suture placement and it appears to be necessary to penetrate the cloacal lumen. The sutures are tied with enough tension to slightly invert the vent. Several other sutures are then placed between the body and cloacal walls. The cloaca also may be sutured to the caudal border of the sternum instead of the ribs if excessive inverting tension is placed on the cloaca when sutured to the ribs. There may be increased discomfort associated with this surgical

procedure when compared to others.^{9,24}

A third cloacopexy technique includes fixing the coprodeum to the abdominal wall. A 2-to 5-mm incision is made in the serosal surface of the coprodeum approximately 5 to 10 mm lateral to the ventral midline of both the right and left sides. Corresponding paramedian incisions are made in the peritoneal surface of the body wall cranial enough so as to result in slight inversion of the vent. Three to four absorbable monofilament sutures are placed in the serosal surfaces of the coprodeum and body wall so as to appose the subserosal surfaces.⁹

An additional cloacopexy technique involves closure of a celiotomy incision to include the cloacal and body wall. The patient is placed in dorsal recumbency and a ventral midline celiotomy is performed. The cloaca is reduced and the lubricated cotton-tipped applicator left in the cloaca to aid in identification and manipulation of the cloaca. Fat is excised from the ventral cloacal surface. The abdomen is closed incorporating the cloacal wall. An absorbable monofilament suture is passed through one side of the body wall, through the full thickness of the cloaca and through the other side of the body wall in a simple interrupted pattern. The overlying skin is closed routinely. Performing the same procedure via a caudal transverse celiotomy approach offers similar benefits, but additionally it avoids incising the cloaca should a future ventral midline celiotomy be necessary.9

CLOACAL MASS EXCISION

Internal papillomatosis is reported in New World psittacine species including macaws, Amazon parrots, hawk-headed parrots and conures. Papillomas may be found on the mucosal surface of the cloaca, oropharynx, esophagus/crop, proventriculus, ventriculus, bile ducts and pancreatic ducts. Cystic regression and recurrence is extremely common and *E. coli* and *Clostridium* spp., are often isolated from the cloacas of affected birds. Surgical removal is recommended, particularly if the mass is causing secondary cloacal infection, fecaliths, hematochezia, cloacal prolapse or if the bird is straining to defecate, indicating a mechanical obstruction. In addition, cloacal leiomyosarcoma has been reported in a blue-fronted Amazon parrot (*Amazona aestiva*). 9,28,68

Methods for removal of cloacal papillomas include silver nitrate cauterization, cryosurgery, radiocautery, laser surgery and excision with a scalpel. The mass and affected cloacal wall may be everted manually and the mass debulked with any of these methods. If silver nitrate is used, the area must be profusely flushed with saline to prevent cauterization of normal mucosa as soon as sufficient tissue has been cauterized to debulk the mass (Figs 35.18a-c).^{1,9}

A cloacotomy may be performed to increase exposure to the affected mucosa and allow complete removal of a large occlusive mass. The patient is placed in dorsal recumbency and the abdomen surgically prepped from the caudal edge of the sternum to the vent. A ventral midline incision with or without a caudal transverse incision is made with a scalpel blade, scissors, radiosurgery or laser through the skin from the mid-abdomen to the ventral vent opening. The underlying vent sphincter muscle and the cloacal mucosa are incised with scissors to expose the entire cloaca. The mass may be removed with chemical cauterization, cryosurgery, radiocautery, laser surgery or excision with a scalpel. When chemical cauterization is used during a cloacotomy, extreme caution must be taken due to increased potential of damage to normal adjacent tissue. Hemorrhage may be controlled with radiocautery. The cloacal mucosa is apposed where the mass is excised with a small, absorbable monofilament suture in a simple continuous pattern. The cloacal mucosa is closed in a simple continuous pattern and the vent sphincter is apposed using a horizontal mattress pattern, both utilizing absorbable monofilament suture. The skin is closed in a simple continuous or interrupted pattern with a monofilament suture. An appropriate antibiotic should be used peri- and postoperatively. Surgical complications may include hemorrhage, scarring, stricture formation, fecal and urate retention, and incontinence. 1,9,23

Mucosal stripping has been reported in a lilac-crowned Amazon parrot (*Amazona finschi*) for removal of cloacal papillomas. Recurrence of the papilloma occurred at the mucosal border adjacent to the sphincter 4 weeks post-operatively and cloacal anatomy was severely disrupted. Significant pain, lethargy, prolonged recovery, weight loss, leukocytosis and stricture of the cloaca also occurred. Therefore, mucosal stripping is reserved for cases where extensive debulking, is necessary. This may need to be done in a step wise fashion; resecting only a portion of the mucosa is less invasive.²

COELOMITIS

Coelomitis may occur secondary to ectopic ovulation, inflammatory and infectious conditions of the gastrointestinal, respiratory and reproductive systems. Many patients will recover with medical therapy and those patients that do require surgical intervention may benefit from medical treatment and supportive care prior to surgery. 12,13,31

If appreciable coelomic fluid is present, it is recommended to either delay surgery or perform an abdominocentesis prior to surgery. Abdominocentesis, if performed, must be accomplished precisely on the ventral midline to prevent coelomic fluid from escaping from

peritoneal cavities and gaining access to the respiratory system. This escape of peritoneal fluid into the air sacs also can occur during celiotomy. This may result in lifethreatening respiratory disease.^{9,24}

The patient is placed in dorsal recumbency with the head and cranial body slightly elevated. Coelomic fluid is aspirated as described above, if indicted a ventral midline celiotomy is performed. A ventral midline approach may avoid transection of the air sacs and any fluid may be suctioned or drained. It may be necessary to adjust the vaporizer setting, as anesthetic depth may be altered when depth of respiration changes. The intestines are retracted atraumatically to gain exposure to the reproductive tract and other coelomic organs. Yolk material and tissue debris are gently removed and the coelomic cavity examined for abnormalities including tissue adhesions.24 A salpingohysterectomy with or without ovariectomy should be performed to prevent future disease. There is risk of respiratory compromise to the patient if air sacs are transected and additional intracoelomic fluid accumulates postsurgically. There often are significant adhesions present between coelomic structures, particularly between the oviduct, and the kidney, ureter and the cloaca. Salpingohysterectomy requires breaking down these adhesions to allow excision of the oviduct. Tearing of these structures and hemorrhage are potential complications. Occasionally oviductal adhesions are too extensive to allow removal of the oviduct. Patients frequently have abdominal distension and muscular dysfunction postoperatively.^{9,24} Some clinicians alleviate this by removing excess muscular tissue or by rolling the muscular tissue to create a muscular stent prior to closure of the coelomic cavity.

Miscellaneous Surgical Procedures

AMPUTATION

Limb amputation appears to be well tolerated by psittacines, however, emotional concerns of the owners often arise and may present a need for careful counseling by the surgeon prior to committing the bird to the surgery. When amputation is recommended not as a result of severe trauma to the bird, but rather due to neoplasia, nonunion fractures or chronic infection, the surgery may be postponed for 1 to 2 days to allow the owner time to reach a decision.

In cases of amputation due to neoplasia or infection, pre-operative radiographs are necessary to assure that affected bone, which may extend proximal to the visibly affected skin and soft tissue, is completely excised.

Prior to performing an amputation, the surgeon should make sure that the surgical team and equipment are prepared for the potentially life-threatening hemorrhage that can occur. At a minimum, a preoperative hematocrit and total protein should be performed to provide an indication of the overall health status of the patient. Extreme care must be taken in small avian patients and patients with a low hematocrit, as death can occur in these patients from the loss of a relatively small amount of blood. The use of a tourniquet is recommended as a means of controlling intraoperative hemorrhage during most amputations. Commercially available rubber smallanimal tourniquets have the potential for causing severe skin trauma. These types of tourniquets can be used if they are well padded. A soft nylon rope, 1/2" rolled gauze, rubber band held by a hemostat, or piece of thick (>1-0) catgut suture provide alternatives. An assistant is necessary to hold the ends of the rope or suture and control the amount of pressure exerted. Ideal pressure will occlude the blood flow to the distal portion of the limb without causing trauma to the skin and underlying tissue. If skin trauma is noted, the placement of the tourniquet must be altered. If it is determined preoperatively that a tourniquet is not to be used, then careful dissection and ligation of the blood vessels is necessary. This may significantly increase the length of the surgery, but is absolutely necessary to prevent hemorrhage. If a tourniquet is not initially applied, it should be kept readily available in the event of severe hemorrhage. Being able to rapidly apply a tourniquet intraoperatively may mean the difference between life and death for an avian patient.5

Appropriate perioperative analgesia will significantly decrease the stress to the patient. If possible, it also is recommended that the avian patient be preconditioned to an Elizabethan collar or "sweater," which will prevent picking at the sutures of the amputation site until the skin is fully healed. Use of these devices and this period of adjustment are especially important for reducing the stress to the patient and decreasing postoperative complications The potential for hemorrhage makes prevention of postoperative picking at the skin and sutures critical.

Amputation of the Wing

When a wing amputation is performed, it is desirable to perform the surgery as distal as possible. This will allow retention of a portion of the normal function of the wing for balance. Some avian patients may traumatize the amputation site and a more proximal amputation site may be necessary. Wing amputation can be divided into three different categories: distal, mid-wing and proximal. A distal wing amputation can be defined as an amputation performed distal to the carpal joint. Indications for this surgery include inoperable neoplasia of the

distal wing, severe trauma or chronic infection. These typically occur in small birds such as budgies, lovebirds or cockatiels, making the need for amputation not uncommon in these species.^{26,40}

Birds weighing less than 150 g should be anesthetized and placed in dorsal recumbency. The feathers distal to the carpal joint should be removed and the area aseptically prepared. Depending on the size of the bird, one or two hemostatic clips can be placed across the distal portion of the carpal joint firmly enough to crush the bone. The portion of the wing distal to the hemoclips can then be removed with a scissors leaving 5 mm of tissue. This small amount of tissue allows for the placement of skin sutures and provides tissue in the event of the hemoclip slipping. The incision is then closed with non-absorbable 5-0 monofilament suture with an atraumatic needle of equal size or smaller than the suture. The hemoclips can typically be removed in 2 to 6 weeks. Appropriate postoperative pain management is necessary. The bird should be observed carefully postoperatively to ensure that it is not picking at the hemoclips or sutures. If necessary, an Elizabethan or tube collar can be applied.^{5,9}

Mid-wing or elbow joint disarticulation is indicated for small to medium-sized birds with trauma, nonunion radial or ulnar fractures, neoplasia or infection of the distal third of the wing. By performing the amputation at this point, the bird will lose its ability to fly but will maintain the use of the wing for balance. The bird should be anesthetized and placed in lateral recumbency. If possible, the feathers 1 to 2 cm proximal and the feathers distal to the elbow joint should be removed and the skin aseptically prepared. A tourniquet can be applied at the level of the mid-humerus to decrease the risk of severe hemorrhage. 9,20,40

A circumferential skin incision is made distal to the elbow joint with a radiosurgical unit, laser or scalpel. Care must be taken to make the incision such that sufficient skin remains to allow closure of the incision. The insertion of the antibrachial muscles and related soft tissues are transected with radiosurgical forceps at the level of the elbow joint. The ligaments of the elbow are transected and the articular cartilage of the humeral condyles is carefully removed with rongeurs or scissors. Horizontal mattress sutures with an appropriately sized, absorbable monofilament suture are used to suture the muscle over the distal humerus. If large vessels are identified, they should be ligated with absorbable monofilament suture. The tourniquet is carefully loosened and the sutured tissue examined for any signs of hemorrhage. Hemostasis can be provided by coagulation with a bipolar radiosurgical forceps, identifying and ligating bleeding vessels, or applying very small hemoclips. The

skin is closed in a horizontal mattress pattern with an appropriately sized, non-absorbable monofilament suture. Placing the suture deep into the muscle is desirable to prevent the possible formation of a hematoma postoperatively. The skin of the wing is very fragile and avoiding the formation of a hematoma may be difficult. It is important to provide postoperative pain management and an Elizabethan collar may be necessary to prevent picking at the incision.⁹

A proximal or proximal-humeral amputation is indicated for chronic trauma to the distal wing, neoplasia, nonunion or open, severely contaminated fractures and severe infection. The bird will lose the ability to utilize its wing for balance, but most psittacines appear to be able to adjust to this without complications. The patient should be anesthetized and placed in dorsal recumbency. The feathers should be removed and the skin aseptically prepared. The distal portion of the wing can be wrapped or covered with appropriate surgical draping material. Application of a soft tourniquet significantly decreases the possibility of severe hemorrhage. The tourniquet should be placed on the proximal humerus. If a mid-humeral amputation is to be performed, the tourniquet should be placed around the shoulder joint, incorporating the insertion of the pectoral muscles. If a proximal humeral disarticulation is to be performed the tourniquet should be placed around the shoulder joint including the brachial plexus.9

A circumferential incision at the mid-humerus is made using a radiosurgical unit, laser or scalpel. It is important to leave sufficient tissues to allow for closure of the skin. Also, it should be noted that despite the presence of a tourniquet, some hemorrhage may occur. Ligatures are placed around the distal portion of the muscles using appropriately sized, absorbable monofilament suture. The suture size should be based on the size of the bird and large enough that when tightened, there is compression without cutting of the tissue. The muscles are then transected at their musculotendinous junctions near the elbow joint using a radiosurgical unit. Blood vessels are identified and coagulated or ligated with 3-0 or 4-0 absorbable monofilament suture prior to being transected. The tourniquet should be loosened and any bleeding vessels ligated or coagulated with the radiosurgical unit. The muscles of the humerus are bluntly dissected from their tendinous attachments to the bone. The humerus is transected in the proximal third of the bone or, alternatively, the proximal humeral joint is disarticulated and the synovial tissues of the glenoid fossa are removed with appropriately sized rongeurs. The pneumatic nature of the proximal humerus makes good tissue coverage of the end of the bone very important. Inserting a piece of gelatin or collagen foam into the

distal portion of the remaining bone will ensure that blood does not travel through the humerus into the rest of the respiratory system. Impregnating this material with an appropriate antibiotic may be useful in preventing or aiding in the treatment of soft tissue or bone infection. The muscles are then sutured over the stump using a horizontal mattress or simple interrupted pattern with 3-0 or 4-0 absorbable monofilament suture. The skin and subcutis are apposed using 3-0 or 4-0 nonabsorbable monofilament suture in a simple interrupted or horizontal mattress pattern. The incision site should be monitored carefully for postoperative hemorrhage. Due to the potential for hemorrhage through the pneumatic portion of the humerus, the patient should be observed carefully for signs of respiratory distress. This surgery can be very stressful to the avian patient and may necessitate several days of hospitalization postoperatively. As with all amputations, postoperative analgesics are imperative (Figs 35.26a-g). Injection of a lidocaine derivative intraoperatively in the area of the radial nerve will also decrease post-operative pain.^{9,40}

Amputation of the Leg

Most companion avian species function well with only one leg, especially psittacines. Care must be taken when considering leg amputation in avian patients. If the leg is amputated distally, the avian patient will attempt to use the remaining stump for ambulation. Contraindications for leg amputation include obesity, osteoarthritis of the contralateral leg or if the bird is unable to utilize its wings to assist in balancing. It is important to provide appropriate perching material to allow ease of grip and prevent perch-associated pododermatitis postoperatively. Amputation is indicated in avian patients with severe non-union fractures, severely contaminated open fractures, neoplasia, severe trauma or infection of the distal leg. Because a large portion of the femur is located within the skin of the body wall, a midfemoral amputation provides for adequate tissue to cover the end of the bone, prevents self-mutilation and is cosmetically acceptable. In captive raptors, postoperative pododermatitis of the contralateral foot is a common sequela, however, it is rarely observed in psittacines fed an appropriate diet and supplied with appropriate perches. 9,20,29,58,74

The patient should be anesthetized, placed in dorsal or lateral recumbency, and the feathers removed from the ventral abdomen distally to the stifle joint. The skin is aseptically prepared utilizing a standard orthopedic technique. The skin incision is made with a radiosurgical bipolar forceps along the web of the knee in the contour of the abdomen and semicircular incisions are made at the level of the stifle. Sufficient skin must remain to provide for closure without undue tension. Ligatures are placed around the distal portion of the muscles using

1-0 or 2-0 absorbable monofilament suture. Blood vessels are identified and ligated with 3-0 or 4-0 absorbable monofilament suture prior to being transected. A periosteal elevator is utilized to elevate the muscles from the proximal femur to the mid diaphyseal region. A bone cutter, osteotome, Gigli wire or other instrument appropriate for the patient's size is used to transect the femur. The muscles are then sutured over the stump with 3-0 or 4-0 absorbable monofilament suture in a simple interrupted or horizontal mattress pattern. The skin and subcutaneous tissues are apposed using 3-0 or 4-0 nonabsorbable monofilament suture in a horizontal mattress pattern. As with proximal humeral amputations, this surgery is very stressful for the avian patient and may necessitate several days in the hospital postoperatively. Appropriate pain management is imperative. 9,58,74

Amputation of the Digit

Toe amputation is indicated in the event of severe trauma, neoplasia, avascular necrosis or infection of any of the digits. The tissue damage may be so severe or multiple toes may be involved such that amputation of the distal portion of the foot is also required. The same surgical techniques are utilized for both the toes and the feet. The patient is anesthetized, placed in dorsal recumbency and the distal portion of the leg aseptically prepped. It should be noted that the avian patient may present to the hospital with a large amount of fecal material on their feet. This requires careful cleaning prior to surgery because of the added risk for contamination and infection of the surgical site. Appropriate postoperative antibiotic therapy is necessary. 9,35

It is possible to perform two types of digit amputations, a proximal joint disarticulation and a phalangeal middiaphyseal amputation. A tourniquet composed of a thick suture material or a soft nylon rope is applied to the mid-tibiotarsal bone to control hemorrhage for both procedures. The site of a joint disarticulation of a digit should be at the joint proximal to the affected area. The skin should be incised distal to the stump to allow for sufficient skin for closure. A bipolar radiosurgical unit or scalpel blade can be used to make parallel horizontal incisions on either side of the toe. Alternatively, an incision is made around the dorsal two-thirds of the toe. It is important not to incorporate the plantar aspect of the digit with this approach. The phalanx is amputated at the proximal end of the bone. The joint may be disarticulated utilizing rongeurs, a scalpel blade, laser or electrosurgical unit. Any exposed joint surface can be removed prior to skin closure. Close in a horizontal mattress pattern with appropriately sized (3-0 to 5-0), nonabsorbable monofilament suture. If a horizontal incision was made, the edges of the skin are apposed with the knot tied on the dorsal surface of the skin. If a plantar

Wing Amputation - Step by Step Figs 35.26a-g

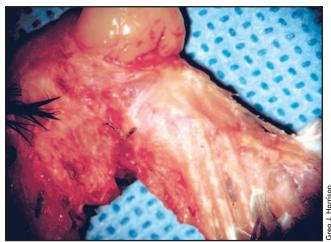

Fig 35.26a | An aggressive tumor involving the carpus was an indication for wing amputation. Harrison prefers to amputate at a joint, thus the elbow was the chosen site.

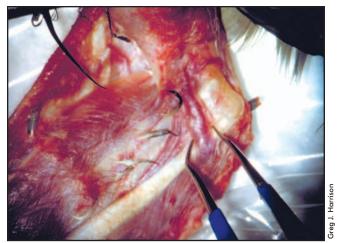

Fig 35.26c | The radiosurgery forceps are placed around the vessel and the coagulation setting is used to seal the vessel.

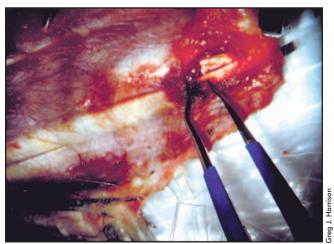

Fig 35.26e | Vessels, ligaments and tendons are transected in a similar manner. Transection of muscle is avoided whenever possible.

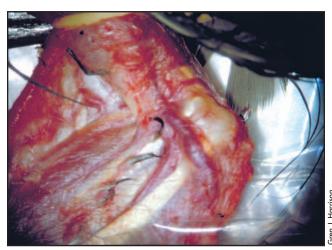

Fig 35.26b | The brachial vein is the first vessel encountered when amputating a wing at the elbow joint. Note the rubber band tourniquet that is secured by a hemostat.

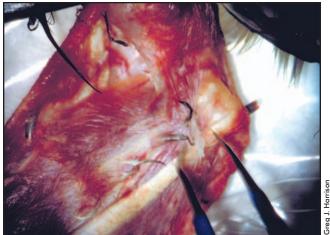

Fig 35.26d | The cutting current is used to incise the vessel and surrounding tissue.

Fig 35.26f | If the upper wing is involved, the wing can be amputated at the proximal ½ of the humerus or at the shoulder joint. Larger diameter vessels in this area will require more extensive and careful ligation. Muscles will require transection, however, sufficient musculature should be retained to cover the remaining portion of humenal bone in the case of amputation at this level. If amputation is performed by disarticulation of the shoulder joint, muscle should be retained and sutured to fill the dead space and prevent seroma formation.

,

ITISON

Fig 35.26g | Skin closure after proximal wing amputation.

skin flap was created, the skin is sutured to cover the end of the bone. Placing the most dorsal suture initially will allow for symmetrical apposition of the sides. The thicker skin of the plantar surface of the toe will provide additional protection for the end of the bone.^{9,35}

A mid-diaphyseal amputation is generally performed on small avian species. The skin is cut proximal to the affected tissue in a circumferential manner utilizing a radiosurgical unit or scalpel blade. The skin is then carefully retracted, exposing the underlying bone. The diaphysis of the bone is transected using rongeurs or scissors. The skin is then pulled distally to cover the exposed bone. Sufficient tissue is removed from the dorsal portion of the remaining skin of the toe to create a flap of plantar skin that will cover the end of the bone. The skin is then sutured using 4-0 or 5-0 non-absorbable monofilament suture in a horizontal mattress pattern. The affected toe and incision should be monitored closely for postoperative signs of infection. An Elizabethan collar or bandaging of the foot, can be utilized to prevent picking at the incision postoperatively.9

ABDOMINAL WALL HERNIA REPAIR

Abdominal wall hernias may be congenital or acquired. The etiology is undetermined, but several disease conditions have been implicated. Hyperestrogenism leading to weakening of the abdominal musculature has been suggested as a predisposing cause in budgerigars (*Melopsittacus undulatus*) and cockatiels (*Nymphicus bollandicus*). Chronically egg-laying hens and changes in calcium metabolism may contribute to muscular atony. Lack of exercise, malnutrition, obesity, space-occupying masses, organomegaly, trauma, or chronic masturbation and straining may result in weakening of the abdominal musculature and abdominal distension.^{9,50,53,56}

Most "abdominal hernias" in birds do not in fact have an opening in the aponeurosis of the abdominal muscles. A true hernia is defined as a protrusion of an organ through connective tissue or through the abdominal wall in which it is usually enclosed. Therefore, a thorough examination is crucial to accurately diagnose an abdominal hernia. Herniation may include separation of the aponeurosis of the abdominal musculature at the ventral midline, allowing coelomic viscera to displace outside the muscular body wall. Clinical signs may include disease associated with entrapment of intestinal loops. "False hernias" or abdominal distension requires investigation of primary etiologies, therefore, a thorough examination and diagnostic protocol is important to accurately assess the patient's condition. In many patients, false hernias are of little clinical consequence and do not require surgery. In addition, surgical repair may carry significant risk. Respiratory compromise may result when reducing the coelomic contents due to increased pressure on the abdominal and thoracic air sacs. Herniorrhaphy is indicated if the abdomen is being traumatized due to distension causing abrasion or ulceration by contact with the perch or floor, herniation of coelomic viscera poses risk to the patient, secondary clinical disease such as egg binding, intestinal obstruction, cloacal urolithiasis or difficulty expressing urates develop. Abdominal hernia and distension have been associated with hepatic lipidosis, reproductive tract disease, intracoelomic lipomas and peritoneal cysts.9,50

Pre-operative radiographs, with gastrointestinal contrast media if needed, will identify the location of structures within the distended or herniated abdomen.

The patient is placed in dorsal recumbency and a ventral midline or an elliptical incisional celiotomy is performed. Caution must be taken when making the midline incision to avoid iatrogenic trauma to underlying viscera. Herniated viscera are gently replaced and the hernia repaired while patient respiration is closely monitored. The distended abdominal wall is trimmed on either side of the linea alba to create a normal anatomic abdominal wall. The abdominal wall is then sutured in a simple interrupted or continuous pattern with absorbable monofilament suture and the overlying skin closed routinely. If the body wall defect is extremely large, a mesh implant may be considered for repair.^{1,9}

ABDOMINAL MASS EXCISION OR BIOPSY

Surgical excision or biopsy of neoplastic masses is indicated for several different types of disease conditions. Removal often requires prolonged anesthesia, strict hemostasis and careful anatomic dissection. This predisposes the patient to hypothermia, hemorrhage and metabolic compromise. Surgical procedure varies with the organ affected. Laser surgery may show some promise for removal of neoplastic and granulomatous masses.^{3,9,51}

When a biopsy and histopathologic diagnosis are obtained, or when complete surgical resection carries an unacceptable risk, alternative treatments may be preferred. Recent advances in oncology, including intralesional cisplatin and carboplatin, have shown promise for various abdominal neoplasias (see Chapter 20, Overview of Tumors).

LIPOMA EXCISION

Lipomas are frequently the result of obesity. Some species demonstrate a predisposition to development of lipomas (see Chapter 13, Integument). Correction of malnutrition, obesity and increased activity level often will reduce the size of lipomas. Medical treatment including supplementation with L-carnitine, or levothyroxine if a hypothyroid condition has been accurately diagnosed, has not met with consistent results. 19,75 It is important to note that liposarcomas, leiomyosarcomas and other masses that mimic lipomas have been reported in pet psittacines. 56

Lipomas that are well encapsulated are generally simple to excise. However, large, diffuse or broader-based lipomas can pose a significant patient risk when excision is attempted. Occasionally, loss of adequate vascular supply will result in central necrosis and ulceration. Large abdominal lipomas may be prone to inadvertent trauma and damage to the overlying skin. The Cavitron ultrasonic surgical aspirator (CUSA) has been used to safely resect lipomas in budgerigars. This ultrasonically powered aspirator selectively fragments and aspirates parenchymal tissue while sparing vascular and ductal structures. Preliminary evaluation suggests that the CUSA may provide reduced tissue necrosis and hemorrhage, increased visibility, shortened operating and anesthetic duration, and reduced recovery time when compared to blade resection, bipolar cautery and CO_2 laser excision.

RENAL BIOPSY

Biopsy of the kidney may be performed through a lateral, ventral midline or combination ventral midline-transverse celiotomy. In addition, a dorsal pelvic approach has been described. Renal biopsy may be performed via laparoscopy. The reader is referred to Chapter 24, Diagnostic Value of Endoscopy and Biopsy for a complete description of this procedure.

Management of

Waterfowl

GWEN B. FLINCHUM, BS, MS, DVM

The order Anseriformes includes swans, ducks, geese and screamers. Numerous excellent references are available for specific medical and biological information on these birds. ^{1,9,11,12,13} Some basic biological facts of which veterinarians should be aware are discussed in the following sections.

Adult male ducks, geese and swans are referred to as drakes, ganders and cobs, respectively. Adult female ducks, geese and swans are called ducks, geese and pens. Young ducks, geese and swans (older than 3 weeks) are referred to as ducklings, goslings and cygnets.

FEATHER CHARACTERISTICS

Molting

Most waterfowl go through a complete molt following breeding season. This molt may last 3 to 6 weeks. During this time, flight feathers are lost, thus the birds are flightless. Most members of the subfamily Anatinae (eg, Shelducks, dabbling ducks, perching ducks, diving ducks) molt twice yearly. Birds of the family Anhimidae (screamers) and the magpie goose (*Anseranas semipalmata*) molt gradually and do not pass through a flightless period.

Feather Color and Sexual Dimorphism

Birds of subfamily Anserinae, ie, whistling ducks, swans, geese, Cape Barren geese (*Cereopsis novaebollandiae*) and freckled ducks (*Stictonetta naevosa*), have plumage that is monomorphic in all species. Magellan geese (*Chloephaga picta*) and kelp geese (*Cloephaga hybrida*) are the exceptions. Greater Magellan ganders have a white head, neck and breast, while females are reddish brown. Kelp geese males are pure white, while females are striped with different hues of brown. Birds of the subfamily Anatinae frequently have dimorphic plumage. Males typically have iridescent coloration with outstanding patterns. Ducks are usually sexually dimorphic

Fig 36.1 | A fence separates two sides of the aviary so birds are able to fly over the fence into the back of the aviary to escape other more aggressive birds.

Fig 36.2 | Back side of a two-sided aviary into which threatened birds may fly.

except for the Pekin, American black duck (*Anas rub-ripes*) and Mexican breeds. It is a hobbyist's theory that male ducks have a curl to their tail feathers at maturity that is not present in females.

ANATOMIC VARIATIONS

Trachea

Swans have an elongated trachea. The trachea of trumpeter swans extends into the sternum, turns on itself and then re-enters the syrinx. The ruddy duck (*Oxyura jamaicensis*) has an inflatable tracheal sac.

Syringeal Bulla

Most male ducks have a left-sided enlargement that can be visualized on radiographs. This is called the syringeal bulla and should not be misinterpreted as pathologic. This structure is absent in swans and geese.

Phallus

Male Anseriformes have an erect phallus that is covered with papillae. By placing gentle pressure on the sides of the cloaca, the phallus can be exteriorized, thus determining the bird's sex as male. Females lack a phallus and instead have two small labia-like structures. Because this type of sexing necessitates turning the bird upside down, geese and swans are most easily done at a young age.

Husbandry

ENVIRONMENTAL/ENCLOSURE CONSIDERATIONS

Enclosed Versus Open Ponds

There are numerous advantages to keeping waterfowl in

enclosed areas. The greatest advantage is protection from outside predators. In addition, it is more difficult for wild birds to enter enclosed areas, and this decreases the chances of introduction of disease into the collection. Another advantage is that birds in enclosed areas do not have to be pinioned. A disadvantage of enclosed areas is that the overall area is smaller than open enclosures, and this may lead to territorial aggression, harassment and injury to smaller birds by more dominant birds. This can be avoided by providing a tiered enclosure in which smaller, less dominant birds can fly up to the second level to escape harassment. It is important to avoid overcrowding in aviaries (Figs 36.1, 36.2).

Nylon netting ab,c works well to enclose pens. In colder areas, the netting will be weighted down with snow or ice, which will cause damage to the netting. This can be corrected by having the netting attached to several wires (Fig 36.3). The wires are then connected to a hand crank. Loosening the netting with the crank alleviates tension, so that damage to the netting is less likely (Lubbock, personal communication^d).

Open ponds provide more space and greater opportunity for grazing. However, birds in open areas are susceptible to predation, especially if they are unable to fly. In some cases, predation can be avoided by enclosing the area with a tall fence lined with electric wire. Furthermore, larger species such as mute swans can be very aggressive and are thus less likely to be attacked.

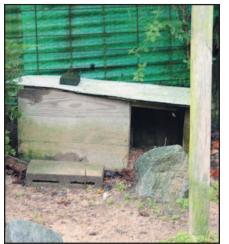

Protection from vermin also is an important consideration. Poisonous bait for rats, mice or roaches can be placed inside long plastic or metal tubes and put outside the reach of birds. However, there have been reports of warfarin toxicity resulting from the birds' ingestion of mouse droppings (Lubbock, personal communication).

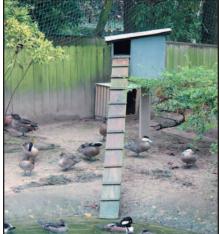

Fig 36.3 | Nets with cable support.

Fig 36.4 | Skirting can be placed around the bottom perimeter of the cage to minimize rodent invasion.

Figs 36.5-36.7 | Various types of houses can be used for waterfowl.

In general, extreme care must be taken when using rodenticides or other poisons near an aviary. Other deterrents for vermin include a 2 to 3 foot (1 m) tall sheet of metal lined with electric wire at the bottom, placed around the bottom perimeter of the cage (Fig 36.4).

Smaller waterfowl can be provided with various types of houses for nesting (Figs 36.5, 36.6). These can be made from large, hollowed-out logs (Fig 36.7) or flat pieces of wood. One breeder has had success using slatted boxes (Fig 36.8) because small waterfowl normally build nests in reeds or grasses, and the staggered pieces of wood in slatted boxes simulate stalks of grasses or reeds. Apparently, this imparts a feeling of privacy and security for birds, thus facilitating nesting (Lubbock, personal communication^d).

Ground cover is an important aspect of enclosure design. Hard surfaces such as concrete should be avoided, as these can contribute to bumblefoot. Grass or dirt surfaces are less irritating to feet, although they are harder to keep clean. A small $(20 \times 20 \text{ feet or } 7.5 \times 7.5 \text{ m})$ swan enclo-

Fig 36.8 | Slatted houses emulate reeds or grasses and impart a sense of privacy for nesting waterfowl.

sure requires twice monthly re-sodding to keep the environment ideal (Montgomery, personal communication^c).

Water Quality

In small enclosures, artificial ponds can be built. These are made of concrete, then painted with waterproof

Fig 36.9 | Small concrete pools are easy to clean and maintain.

Fig 36.11 | Water aerator for a large pond.

Fig 36.10 | Swans and diving ducks require ponds 3–4 feet deep.

Fig 36.12 | Reeds and water plants can be useful in water filtration.

epoxy pool paint (Fig 36.9). These types of pools can be drained and cleaned on a regular basis. A water depth of 2 feet is adequate for most Anseriformes. Swans and diving ducks require 3 to 4 feet of water (Fig 36.10). Water quality in larger ponds is affected by the amount of ammonia present. Ammonia forms near the bottom surface of the pond subsequent to the degradation of fecal matter, food and other organic substances. It then rises to the surface of the pond where it facilitates algae growth. Above-water aerator systems can be utilized to remove ammonia before it reaches the pond surface. A network of underwater pipes that is connected to a central fountain achieves this (Fig 36.11). The pipes carry water (and thus ammonia) from the bottom surface area to the fountain where it is discharged into the air. This eliminates ammonia and oxygenates the water, which results in cleaner, fresher water with less algae.

Filtration systems also can be utilized to maintain water quality. There are hundreds of systems available and many of these can be researched on the Internet. The majority of these are for smaller ponds, with 25,000-

gallon capacities being maximum size. Submersible filters are very effective in maintaining water quality. However, care must be taken when using these, as there have been reports of birds being pulled under water and trapped in the filtration system. Reeds and water plants can act as natural water filters when placed at exit and entry points of water flow (Fig 36.12). If water quality becomes out of balance—usually too much nitrogen and phosphorous combined with warm weather and bright sunlight—algae will bloom. A dark blue coloring agent⁸ that blocks the light so algae cannot grow is available.

Species Compatibility

In general, the smaller the enclosure area, the more potential there is for territorial aggression. As previously mentioned, tiered cages will allow smaller species to fly away from more aggressive birds. Inbreeding can occur and should be avoided. Likewise, interspecies breeding is undesirable and can be avoided by not having many different species of geese or ducks in one pen. Table 36.1 lists waterfowl species that should not be mixed.

Table 36.1 | Waterfowl Species That Should Not Be Housed Together

Keep Isolated as a Single Pair	Exceptions	Specific Non-mix Combinations
Swans, especially: • Coscoroba	Two pairs of black swans may be kept together if the area is large enough, as long as they are released together. Never release a young pair into the territory of an established pair.	Even on large lakes, never mix two pairs of trumpeter swans. Never mix a pair of Bewick's swans with a pair of whistling swans.
Ducks, especially: Screamer Bronze-winged Pink-eared Hartlaub's Comb Shelducks White-winged wood Musk Crested New Zealand teals (brown teals or brown ducks)	More than one pair of comb ducks and white-winged wood ducks can be released together if the area is large, but do not release new birds into an existing group. Never release a young pair into the territory of an established pair.	Avoid keeping any subspecies together.
Geese, especially: • Sheldgeese (Andean) • Egyptian • Cereopsis geese • Spur-winged	Never release a young pair into the territory of an established pair.	Hawaiian geese (Néné) and cackling Canada geese. Avoid keeping any subspecies together.

Fig 36.13 | Royal mute swans (Cygnus olor).

Fig 36.14 | Black swans (Cygnus atratus).

Species Considerations for a Collection

Choosing which waterfowl to have in a collection depends on a number of considerations. These include price and availability of birds, aggression quotient (ie, larger birds such as swans can be quite aggressive during mating season), susceptibility to predation (smaller, pinioned birds are more likely to be attacked) and size of enclosure and water quality. Figs 36.13-36.18 show some commonly kept swans.

Banding Birds

Once birds are acquired, placing leg bands is recommended, especially if there are two or more birds. This helps identify birds for breeding and health monitoring. Bands that are placed on the upper part of the leg (on the tibiotarsus) have a lesser chance of getting caught and causing injury (Fig 36.19). In addition, bands can be

placed on the left leg of females and the right leg of males for quicker sex identification. Plastic leg bands have an advantage over aluminum because they are expandable (Fig 36.20). Aluminum bands can become bent, thus placing pressure on the leg or causing constrictions. Metal leg bands increase the incidence of frostbite injury in cold climates.

Diet

There are several commercially formulated diets available for waterfowl. h,i,j These simplify meeting growing, maintenance and breeding nutritional requirements. Waterfowl kept on corn and lettuce diets frequently have dietary deficiencies that manifest as joint pain/lameness and bumblefoot. Grass and plants should be available for foraging.

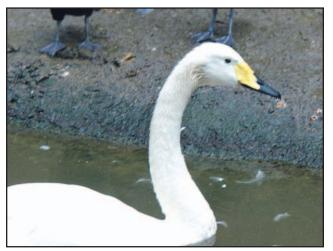

Fig 36.15 | Whooper swan (Cygnus cygnus).

Fig 36.17 | Coscoroba swans (Coscoroba coscoroba).

Fig 36.19 | Bands placed on the upper part of the leg have less chance of becoming entrapped.

Fig 36.20 \mid Plastic leg bands are suitable for identification of waterfowl.

Fig 36.21 | A 50-foot ski rope can be wound on a reel to be used for swan capture.

Fig 36.23 | The rope is stretched across the pond and moved toward the swans.

Fig 36.22 | Rope-across-pond method of capturing swans: one person stands on each side of the pond holding an end of the rope.

Fig 36.24 | As the rope is moved toward the swans, they are herded in the desired direction for capture.

Management of Patients

CAPTURE AND RESTRAINT

Capturing pinioned waterfowl for examination in an open environment can be challenging. Most are excellent swimmers but are not proficient runners; therefore, a primary goal is to manipulate the birds out of the water so they can be more easily captured on land. This can be accomplished in a number of ways.

Capture Methods

Rope-across-pond Method

This method (Figs 36.21-36.23) involves pulling a long rope across the diameter of the pond. The birds attempt to swim away from the rope and can be herded up onto shore (Fig 36.24). A 50-foot (yellow) nylon ski rope can be purchased from a hardware or boating store. This can be wound upon a reel (such as that used to wind an electrical extension cord) for easy access (see Fig 36.21).

If a longer length is needed, two cords can be spliced together. A disadvantage of this method is that birds will quickly overcome their fear of the rope and learn to swim under or over the rope to avoid capture.

Net Restraint

Pole nets^k can be used to capture waterfowl (Fig 36.25). This method actually works well for capturing swans and geese from a small boat.

Throw Nets

Circular nets with a weighted outer perimeter can be thrown over birds (Fig 36.26). These are best used on land or in very shallow water. Throw nets should be inspected prior to use and damaged weights removed to avoid lead weights falling off in the pond.

Manual Capture

Swans and geese can be grasped gently but firmly by the base of the neck, then covered with a towel to prevent injury from the wings to the handler. Both large and

Fig 36.25 | A pole net can be used for capturing waterfowl.

Fig 36.27 | Waterfowl can be restrained by grasping the humerus on each wing at the shoulder. Such restraint applied on the lower wing can result in injury.

Fig 36.26 | Circular throw nets can be used for capture on land.

Fig 36.28 | Large waterfowl should be carried under the arm with the head facing backward. Additionally, the head can be covered to avoid bites.

small waterfowl can be restrained by holding the base of the wings (Fig 36.27). Smaller birds can be carried in this manner; however, larger birds should be carried under one arm with the head facing backward and the body and feet supported with the other hand (Fig 36.28).

Restraint for Travel

Birds can be wrapped in a towel or pillowcase (Fig 36.29), then encircled with cohesive flexible bandage material.^m Caution should be taken so that the bird is not wrapped too tightly. In addition, birds should be monitored for overheating in hot weather.

Drug Immobilization

Chemical immobilization has been reported for use in waterfowl; however, this has not proven to be an effective adjunct to capture for many reasons. Drugged birds may go into the water and subsequently drown. When oral agents are mixed with food, over-consumption may cause an overdose with subsequent death. In addition,

Fig 36.29 | Large waterfowl can be wrapped in a pillowcase to restrain for travel.

recovery from such drugs may be prolonged and may take up to 8 hours.

Fig 36.30 | Feathers of a healthy swan.

Fig 36.32 | Bumblefoot in a mute swan.

Fig 36.31 | Frayed, dirty feathers of an unhealthy bird.

Fig 36.33 | The feet of healthy swans have no cracked areas or lesions.

Dangers to Handlers During Capture and Restraint of Swans and Geese

Wings

Swans and geese use wings defensively. The distal humerus and olecranon can cause contusions. It is important to avoid having the handler's head anywhere near the wings, as serious injury can occur. This is true with any large bird, but especially dangerous when handling the spur-winged goose.

Toenails

Waterfowl have short but very sharp toenails. These can cause painful scratches.

Beak

Most waterfowl have serrations on the edges of their beaks. They are capable of causing bruises when they bite or pinch. Handlers also must beware of the potential for an eye injury from biting birds.

PHYSICAL EXAMINATION

Feather Quality

Feathers should be smooth and regular in appearance

(Fig 36.30). Frayed, dirty, bent or broken feathers may indicate lack of preening or abnormal molting (Fig 36.31). Water should roll off normal feathers, and feathers should not have a wet appearance. Feather color should be consistent, ie, white feathers should be white, not brown or dirty.

Skin and Foot Quality

The skin is best examined over the chest muscle and on the feet and legs. Skin should not be cracked or flaky. The bottoms of the feet should be examined for bumble-foot lesions (Fig 36.32). Ideally, the bottoms of the feet should have small patterns of scale with no balding areas or scabs (Fig 36.33). Limping is generally a sign of joint or foot problems.

Body Weight

General body weights for waterfowl are available in table form. Body weight should be recorded at every physical exam. Deviations from previously recorded weights may indicate disease. Many free-ranging waterfowl have palpable keel bones. A prominent keel bone indicates

excessive weight loss with probable disease. Large birds can be easily weighed using a human scale; obtain the holder's weight and then hold the bird, subtracting the difference of the two weights. This is an ideal way to weigh larger species.

Eyes, Nose, Mouth

Eyes should be clear with no redness or discharge. In collections where inbreeding is allowed, ocular abnormalities may be seen (corneal or ocular opacities). The nares should have no discharge and be bilaterally symmetrical. The oral cavity should be examined and should be free of excessive redness, white plaques or brown mucous. Breathing should not be open-mouthed or labored. Auscultation of lungs and air sacs should reveal little or no sound. Wheezing or crackling may indicate respiratory illness.

Feces

It is not unusual for waterfowl to have some loose feces, however, feces should not have a foul odor. Fecal color should be brown but will depend on diet. Excessively green feces, urine and urates may indicate liver disease.

Overall Behavior

Sick birds will sequester themselves away from other birds. Often, sick birds will be at the bottom of the pecking order, so their feathers will be more dirty, plucked and ragged than those of other birds. Another indication of illness is reluctance get up and move around. Sick birds spend inordinate amounts of time lying down or sleeping. Male swans will harass female and juvenile birds in an attempt to mate. If not interrupted, some infirm birds have been drowned by aggressive males.

TESTING RECOMMENDATIONS

Blood Testing

The recommendations for blood tests in waterfowl are similar to those commonly performed in other birds and include the following: complete blood count, advanced serum chemistry panel with bile acids, serum protein electrophoresis, chlamydial PCR testing and aspergillosis serology. Chlamydiosis serology has not been rewarding in waterfowl.

Blood Collection

The safest place for blood collection is the medial metatarsal vein (Fig 36.34). The cutaneous ulnar vein also can be used but there are more problems associated with using this vein. For example, birds do not like having the wing restrained and tend to struggle more during wing venipuncture. This can lead to head injury to the handler. Furthermore, hematoma formation is more

Fig 36.34 | Blood is easily collected from the medial metatarsal vein.

likely when using the cutaneous ulnar vein. The jugular vein is not commonly used for blood collection due to difficulty in visualization of the vein, especially in longnecked birds.

Blood Parameters

Hematology and serum chemistry values for waterfowl are listed in Table 36.2.

Fecal Tests

Direct fecal smears are a simple way to check for internal parasites. This is easily done by smearing a small amount of fresh feces on a microscope slide, adding a few drops of lactated Ringer's solution, adding a cover slip and examining under a microscope. *Giardia* spp. or other protozoan organisms as well as parasite eggs can be visualized on direct fecal smears. Fecal Gram's stains can be used to identify *Cryptosporidia* spp. and budding yeast. Gram-negative bacteria and *Clostridia* spp. are not unusual in Gram's stains of asymptomatic waterfowl and should not necessarily be treated.

Endoscopy

Endoscopy is routinely performed via the left or right lateral approach as with parrots. Because swans and geese have elongated tracheas, tracheal endoscopy is difficult, since few endoscopes will reach far enough to visualize the trachea in its entirety. A flexible endoscope can be used, as the trachea of most birds over 1000 g will pass a 3-mm scope.

Other recommended diagnostic tests include radiology, histopathology, necropsy and culture and sensitivity of feces, throat or skin lesions.

TREATMENT RECOMMENDATIONS

Fluid Therapy

Intravenous catheterization can be most easily done in the medial metatarsal vein. This vein is easy to access and not highly prone to hematomas, and birds tolerate catheter placement well there. The biggest disadvantage of using the medial metatarsal vein is that some agents injected into the legs will go through the renal portal system and be excreted by kidney tubules before entering the general circulation.8 However, the author has experienced successful treatment results following fluid and antibiotic therapy administered via this method. Catheter placement is implemented in the same manner as with dogs and cats. A 20- to 24-gauge Teflon catheter can be used. It is recommended that catheters not be left in for more than 48 hours. If long-term catheterization is necessary, a vascular access device may be necessary.6 Catheterization also may be done in the cutaneous ulnar vein;

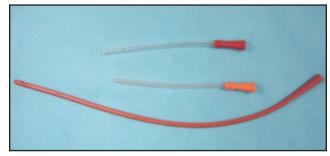

Fig 36.35 | Red rubber catheters or silicone feeding tubes can be used for gavage-feeding waterfowl.

however, as previously mentioned, there is a greater possibility of hematoma, and this is more dangerous to the handler in larger birds. Jugular catheterization is difficult due to visualization difficulties discussed earlier.

Intraosseous catheterization can be performed in the tibiotarsus or ulna but is more painful than intravenous catheterization. Such catheter placement often necessitates anesthesia, and some patients may not be candidates for anesthesia. Bone infection may occur if the process is not done aseptically.

If a patient is not hypoproteinemic, subcutaneous fluids with hyaluronidaseⁿ have been preliminarily purposed to be as effective as intravenous fluids.⁵

Oral fluids should also be given in tube-feedings in mildly dehydrated birds.

Gavage-Feeding

Soft tubes work well for gavage feeding waterfowl. Swans and geese can be gavage fed with 14-Fr (16") red rubber catheters.^{o,p} Smaller birds can be fed using silicone feeding tubes^{o,p} (Fig 36.35). There are a variety of formulas available for nutritional support in debilitated patients.^q

Medications

Table 36.3 lists medications commonly used for waterfowl.

SURGICAL PROCEDURES

Pinioning

Pinioning, the surgical removal of the tip of the wing from the alula distally to render a bird flightless, is a common procedure in waterfowl. When done early (at 2-3 days old), this procedure is virtually bloodless and stress free (Figs 36.36-36.38). Pinioning older birds is more difficult because stress and excessive bleeding can occur. The proper technique for pinioning is to remove metacarpals III and IV and leave the alula intact to cover the amputated area. If the alula is removed, repeated trauma to the stump can occur on a regular basis.

Table 36.3 \mid Medications Commonly Used for Waterfowl

Generic	Trade Name(s) and Manufacturer	Dosage(s) and Route(s)	Main Indications	
ANTIBACTERIAL AGENTS				
Amoxicillin	Amoxinsol 50 soluble powder (Univet)	1 g/3 L drinking water* Medicated drinking water should be provided on alternate days for 3 days, ie, 2 days of medication.	Sensitive bacterial infections	
Chlortetracycline	Aureomycin soluble powder (Cyanamid)	1000 ppm (18.2 g/kg feed) in feed for 45 days	Chlamydiosis	
Co-trimazine (trimethoprim + sulfadiazine)	Cosumix Plus soluble powder (Ciba); Duphatrim Poultry Suspension (Solvay Animal Health) (Bactrin, Roche)	1 ml/5 L drinking water* for 5-7 days	Sensitive bacterial infections	
Doxycycline	Ronaxan tablets (Rhône Mérieux) (Henry Schein, Roerig)	50 mg/kg PO BID for 3-5 days (45 days for chlamydiosis) or 240 ppm in feed for 45 days	Sensitive bacterial infections, especially chlamydiosis	
	Steriject (Pfizer)	75 mg/kg IM once weekly for 6 weeks	Chlamydiosis	
Enrofloxacin	Baytril 2.5% or 5% injection 2.5% or 10% oral solution or tablets (Bayer) (Baytril 2.7%, Haver/Diamond)	10-15 mg/kg IM or PO BID for 5-7 days 4 mg in 20 ml saline for a 1-kg bird –	Sensitive bacterial infections. Useful for bacterial hepatitis or septicemia in neonates. Used widely in growing chickens and poultry of all ages without any incidence of articular cartilage problems: at normal therapeutic levels (10-15 mg/kg BID) it is unlikely to produce joint deformity in neonatal waterfowl (or in raptors or pigeons). Treatment of sinusitis	
		daily nasal flushing for 10 days		
Lincomycin	Lincocin soluble powder (Upjohn)	10 g/5 L drinking water* for 5-7 days	Pasteurellosis, mycoplasmal tenosynovitis	
Lincomycin/spectinomycin	Linco-Spectin 100 soluble powder (Upjohn)	3 g/4 L drinking water* for 3-7 days	Mycoplasmal tenosynovitis, sinusitis	
Oxytetracycline	Various long-acting injections.	200 mg/kg IM daily for 5-7 days	Pasteurellosis and other sensitive bacterial infections	
	Terramycin soluble powder (Pfizer)	37 g/15 L drinking water* for 5-7 days		
Tylosin	Tylan 50 or 200 injection (Elanco) (Butler)	20-30 mg/kg IM TID for 3-7 days; or 100 mg in 10 ml saline, daily nasal flush for 10 days.	Mycoplasmosis	
	Tylan tablets (Elanco)	20 mg/kg PO TID for 3 days		
	Tylan soluble powder (Elanco)	2.5 g/5 L drinking water* for 3 days		
ANTIFUNGAL AGENTS				
Itraconazole	Sporanox capsules (Janssen)	10 mg/kg PO SID for 7-10 days for prophylaxis, or BID for 4-6 weeks for therapy	Aspergillosis	
Nystatin	Nystan oral suspension (Lagap) (Myco 20, Squibb)	300,000 units (3 ml)/kg PO BID for 7 days	Candidiasis	
ANTIPROTOZOAL AGENTS				
Clazuril	Appertex (Harkers)	5-10 mg/kg PO every 3rd day on 3 occasions	Coccidiosis	
Co-trimazine (trimethoprim + sulfadiazine)	Cosumix Plus soluble powder (Ciba); Duphatrim poultry suspension (Solvay Animal Health) (Bactrin, Roche)	60 mg/kg (combined constituents) PO BID, 3 days on, 2 days off, 3 days on	Coccidiosis Do not use in dehydrated birds	
	Duphatrim 24% injection (Solvay Duphar)	30 mg/kg SC, 3 days on, 2 days off, 3 days on		
Pyrimethamine	Daraprim (Glaxo-Wellcome)	0.25-0.5 mg/kg PO BID for 30 days	Sarcocystis spp., toxoplasmosis	
Pyrimethamine/ sulfaquinoxaline	Microquinox (C-Vet Livestock Products)	60 mg/L drinking water*, 3 days on, 2 days off, 3 days on	Coccidiosis	
Toltrazuril	Baycox (Bayer) (Bayvet)	1 ml of 2.5% solution/2 L drinking water* for 48 hours	Coccidiosis	
ENDOPARASITICIDES				
Chlorsulon	Curatrem (MSD Agvet)	20 mg/kg PO 3 times at 2-week intervals	Control cestodes and trematodes	
Fenbendazole	Panacur 2.5% or 10% liquid, 8-mg capsules (Hoechst)	20 mg/kg PO once	Control nematodes	
Flubendazole	Flubenvet (Janssen)	240 ppm (2.4 kg/ton) in feed for 7 days	Control nematodes	
Ivermectin	Ivomec 1% cattle injection (MSD Agvet)	200 μg/kg SC or PO once	Control nematodes and nasal or duck leeches	
Levamisole	Various, eg, Levacide (Norbrook) (Ripercol-L, American Cyanamid)	25-50 mg/kg SC once	Control nematodes	

Table 36.3 | Medications Commonly Used for Waterfowl (Continued)

Generic	Trade Name(s) and Manufacturer	Dosage(s) and Route(s)	Main Indications
ENDOPARASITICIDES (continued)			
Mebendazole	Mebenvet (Janssen) (Telmin,	5-15 mg/kg PO daily for 2 days	Control Syngamus trachea
	Pitman-Moore)	120 ppm (1.2 g/ton) in feed for 14 days	Control nematodes
Praziquantel	Droncit (Bayer) (Bayvet)	10-20 mg/kg SC or PO once. Repeat after 10 days	Control cestodes
		10 mg/kg SC or PO daily for 14 days	Control trematodes
MISCELLANEOUS	-		-
Atropine	Atropine injection (C-Vet)	0.1 mg/kg IV or IM every 3-4 hours	Anticholinesterase poisoning, eg, carbamate
D-penicillamine	Distamine (Dista) (Cupramine, Merck; Depen, Wallace; Titratabs, Wallace)	55 mg/kg PO BID for 7-14 days	Heavy metal poisoning
Dexamethasone	Dexafort (Upjohn)	2 mg/kg SID for 2 days only	Treatment of shock, or anti- inflammatory
Diazepam	Valium (Roche)	0.5-1.0 mg/kg IV or IM, BID or TID, as required	Control of fits
Dinoprost tromethamine (PGF 2, alpha), PGE _{1or 2}	Lutalyse (Upjohn)	0.02-0.1 mg/kg IM or topically onto cloacal mucosa, once	Egg binding
Doxapram	Dopram injection (Willows Francis) (Robins)	10 mg/kg IV once	Respiratory stimulant
Iron dextran	Vet Iron injection (Animalcare) (Butler, Lextron, Vedco)	10 mg/kg IM. Repeat in 1 week	Anemia
Ketoprofen	Ketofen (Rhône Mérieux) (Fort Dodge/Aveco)	1 mg/kg IM SID for 1-10 days	Pain relief, arthritis
Magnesium sulfate crystals	Magnesium sulfate (various)	0.5-1.0 g/kg PO SID for 1-3 days	Increase gut motility. Aid passage of lead if present in intestines
Metoclopramide	Emequell (Pfizer) (Reglan, Robins)	2 mg/kg IV or IM TID as required	Anti-emetic. Control of gut stasis, eg, sour crop
Oxytocin	Oxytocin S (Intervet); Oxytocin (Leo) (Butler, Lextron, Vedco)	3-5 IU/kg IM	Egg binding
Pralidoxime mesylate	Contact National Poisons Bureau regarding availability (Protopam, Wyeth-Ayerst)	100 mg/kg IM. Repeat once after 6 hours	Organophosphate and acetyl- cholinesterase poisoning, eg, carbamate
Sodium calcium edetate	Sodium Calcium edetate (Strong) (Animalcare) (Calcium Disodium Versonate, 3M Pharmaceuticals)	10-40 mg/kg IV or IM BID for 5-10 days with concurrent fluid therapy	Lead poisoning. No need to dilute

Reproduced from BSAVA Manual of Raptors, Pigeons, and Waterfowl, edited by Peter H. Beynon, Neil A. Forbes and Nigel H. Harcourt-Brown (1996) with permission of BSAVA.

Another advantage to pinioning birds at a young age is that birds can be easily sexed before pinioning. Subsequently, the wing pinioned can indicate the sex of the bird, ie, females will be pinioned on the left wing and males will be pinioned on the right.

Tendonectomies of the *extensor carpi radialis* tendon or the insertion point of the superficial *pectoralis* muscle are surgeries that have been described for rendering birds flightless. These techniques are not always effective. Furthermore, most waterfowl owners feel that it is not cost effective to do these surgeries.

Displaced Tendon Repair (Luxation of the Achilles Tendon)

Surgeries have been described for the repair of Achilles tendon luxation.^{2,9} Depending on the cause (which is often due to malnutrition), prognosis for recovery is poor, especially in heavier birds. Placement of the

affected bird in a sling apparatus to take weight off the legs may improve prognosis.

Orthopedic Repairs

Leg fractures in swans and geese may carry a more guarded prognosis for healing due to large body size and short legs. Immobilization is imperative and may cause stress to the patient. Otherwise, fracture treatment and repair is identical to that done in other birds.

Reproduction

Average Biological Data

Table 36.4 lists sexual maturity, clutch size and incubation period of various waterfowl.

Generally incubation periods are: ducks, 28 to 30 days;

^{*}Ed. Note - To be effective, drink water medication needs to be administered to waterfowl with no water to swim in and the source elevated to avoid bathing.

Fig 36.36 | Cygnets if they are to be pinioned it should be done at 2 to 4 days of age.

Fig 36.38 | Pinioning metacarpals III and IV are cut as close to the alula as possible with sterile clippers.

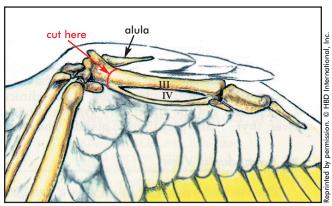

Fig 36.37 | Anatomy for pinioning. The alula is identified as a landmark and spread away from the carpus. Metacarpals III and IV are shown.

Table 36.4 | Waterfowl Reproductive Data

Species	Sexual Maturity (years)	Clutch Size	Incubation Period (days)
Mute swan	5	4-8	35-40
Pink-footed goose	2	3-5	26-27
Bar-headed goose	2	4-6	27
Hawaiian goose	2	3-5	29
Red-breasted goose	2	3-7	23-25
European wigeon	1	7-11	23-25
Mallard	1	8-12	23-29
Common eider	1	3-6	25-30
Tufted duck	1	6-14	23-25
Mandarin duck	1	9-12	28-30
Muscovy duck	1	8-15	35
European goldeneye	1	9-11	27-32

geese, 20 to 28 days; swans, 30 to 40 days; and Shelducks, 27 to 30 days.

Age of Sexual Maturity

Most ducks are sexually mature at 1 year of age. Geese usually mature in about 2 years. Swans reach sexual maturity at about 5 years.

Artificial Incubation

There are a variety of incubators (Fig 36.39, 36.40), brooders and hatchers (Fig 36.41) available that are suitable for waterfowl. *rs.ru* For artificial incubation in waterfowl, incubator temperatures of 99.3° F (37.3° C) and 85% humidity are desirable.

Brooder rooms should be designed so they are easy to clean with adequate ventilation, heating and cooling capacities (Fig 36.42). A heat source (such as a 150-watt heat lamp) should be provided in one area such that the young birds can get close to or back away from the heat as needed. The temperature should be about 95 to 99° F (35-37.2° C) initially, and then gradually decreased over a 3-week period. 9 Never allow chicks to become chilled.

Food and water should be placed at the end opposite from the heat source. Large colored marbles may be placed in water dishes to encourage the birds to learn how to drink. It is not advisable to use hay, shavings, straw or newspaper in the enclosure, as these may be consumed.

Young birds may be ready for outside pens at 2 to 4 weeks of age. Concrete pens with epoxy-painted pools can be constructed. Shallow pools three-fourths inch deep are recommended to acclimate the young birds to water (Fig 36.43). A heat source can be provided in the pen. The pens pictured have doors that can open to outside pens (Fig 36.44). These help acclimate birds as they are going from the controlled indoor environment to the less-controlled environment of outside pens. Once acclimatized to the outdoor pens, the birds can then be moved to larger growing pens.

Waterfowl Diseases

An extensive table of bacterial, fungal, viral and parasitic diseases of Anseriformes is available elsewhere ⁹ Listed

Figs 36.39, 36.40 | Different types of incubators are available for waterfowl.

Fig 36.41 | Hatcher for waterfowl eggs.

Fig 36.43 | Shallow ponds help acclimate young birds to water.

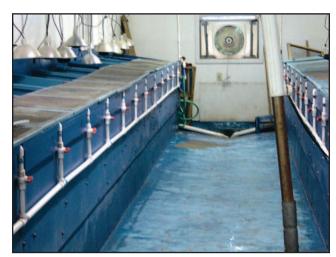

Fig 36.42 | Brooder room.

Fig 36.44 | Indoor pens that open to outdoor pens make excellent transition housing.

Fig 36.45 | Heart of a mute swan with gout secondary to bacterial septicemia.

Fig 36.46 | Angel wing in an adult Abyssinian blue-winged goose (Cyanochen cyanopterus).

below are some of the most commonly observed disease syndromes.

Malnutrition

Dirty, broken, frayed feathers that do not repel water effectively evidence malnutrition. Frequently, affected birds have secondary bumblefoot due to dietary insufficiencies. Leg and joint lameness with a reluctance to move are other clinical signs, especially in younger birds. Hepatic lipidosis is common in malnourished birds. These birds also are frequently immunosuppressed and thus have secondary bacterial infections. The use of balanced, formulated diets appears to mitigate, if not alleviate, many of these clinical signs.

Bumblefoot

Many waterfowl with bumblefoot (see Fig 36.32) show no signs of lameness. In fact, many cases are not noticeable until the bird is restrained and examined. The underlying cause is usually malnutrition, although rough surfaces and excessive egg laying also can be contributing causes. Because bumblefoot is usually a chronic inflammatory condition, amyloidosis is a common sequela.

Trauma

Most of the larger waterfowl cannot survive if injury, such as that incurred from a dog, alligator, raccoon or turtle attack, results in the disuse of one leg. Heavy body size is not supported well by the one remaining leg. *Pasteurella multocida* is a frequent concern from scratch or bite wounds of predators.

Amyloidosis

Amyloidosis is a condition in which normal organ cells are replaced with a proteinaceous amorphous, eosinophilic, acellular material. Although the exact pathogenesis

is unknown, amyloidosis is thought to be associated with stress of close confinement, chronic primary diseases or inflammatory conditions. Acute death frequently occurs, and liver and kidney biopsies are currently the only antemortem diagnostic tests. Where clinical signs occur, affected birds appear lethargic, have a lack of appetite, and are reluctant to stand. Gout is seen frequently subsequent to kidney failure associated with amyloidosis.

Gout

Gout (Fig 36.45) occurs secondary to renal failure. Causes of renal failure include toxicoses, chronic infection and amyloidosis.

Angel Wing

Angel wing (Fig 36.46) is a condition in which the distal portion of the wing appears flipped outward. Young swans and geese are most susceptible to this condition. Angel wing is caused by excessively rapid growth of feathers in relation to muscle development. As a result, growing flight feathers cause excess stress (weight) on carpal muscles, making the carpal portion of the wing hang and twist outward. Possible causes for angel wing include manganese or vitamin E deficiency, hypovitaminosis D₃, genetic factors, over-feeding and excessive dietary protein. If angel wing is noticed soon after the condition develops, it may be corrected by taping the wing in a normal position for 3 to 5 days. However, if the condition is left uncorrected until adulthood, the carpus can become traumatized, with amputation the best solution.

Non-specific Joint Inflammation/Lameness

Clinical signs of non-specific joint disorders include lameness or reluctance to move. This is seen frequently in young birds that are fed primarily "scratch grains"

(cracked corn, wheat, barley or oats) or large amounts of lettuce. In these cases, improvement is seen when the birds are switched to a pelleted diet. This condition also is seen in older birds (especially swans) as arthritis or septic joint infections. Depending on the cause, some decrease of pain and inflammation can be seen with flunixin-meglumine (1-10 mg/kg IM). Carprofen (5-10 mg/kg PO q 24 h) also may be effective. Frequently, bumblefoot develops or worsens as a result of excessive weight placed on the unaffected leg.

Fire Ant Stings

Fire ants are common in Florida. Stings manifest as necrosed areas on the foot web. When healed, these areas show up as defects in the foot web. In the aviary, 5% carbonate dust will help control fire ants. Improperly applied this can be toxic to birds.

Maggot Infestation

Maggot infestation occurs when old wounds (cuts or bites) go undetected or neglected. Infestation can occur in as few as 24 hours. Hydrogen peroxide helps flush out maggots, or they can be removed manually with forceps. Prognosis for tissue recovery depends on the amount of necrosis and length of time the wound has been left

unattended. Carcasses that harbor maggots may be a source of botulism toxins if maggots are consumed.9

Management of

Racing Pigeons

JAN HOOIMEIJER, DVM

Open flock management, which is used in racing pigeon medicine, assumes the individual pigeon is less important than the flock as a whole, even if that individual is monetarily very valuable. The goal when dealing with racing pigeons is to create an overall healthy flock composed of viable individuals. This maximizes performance and profit. Under ideal circumstances, problems are prevented and infectious diseases are controlled. In contrast, poultry and (parrot) aviculture medicine is based on the principles of the closed flock concept. With this concept, prevention of disease relies on testing, vaccinating and a strict quarantine protocol — measures that are not integral to racing pigeon management.

This difference is due to the very nature of the sport of pigeon racing; contact among different pigeon lofts (pigeon houses) constantly occurs. Every week during the racing season, pigeons travel — confined with thousands of other pigeons in special trucks — to the release site. Pigeons from different lofts are put together in baskets. Confused pigeons frequently enter a strange loft. In addition, training birds may come into contact with wild birds during daily flight sessions. Thus, there is no way to prevent exposure to contagious diseases within the population or to maintain a closed flock. The pigeon fancier also must be aware that once a disease is symptomatic, the contagious peak has often already occurred, so preventive treatment is too late. Treatment at this point may be limited to minimizing morbidity and mortality.

Fig 37.1a | The appearance of the head of a "modern" male racing pigeon, is a result of selective breeding. The differentiation of the sexes of the modern racing pigeon by head structure has become much less dependable than in the wild type.

Fig 37.1b | The head of an "old fashioned" or "show racer" male pigeon makes visual sexing easy.

What Makes a Loft Successful?

OUALITY OF THE PIGEONS

The health and racing abilities of racing pigeons are limited by the genetics of the parents. This selection process has even altered the appearance of the birds (Figs 37.1a,b). Using strong selection criteria when pigeons are paired ensures that the quality increases with each successive generation. Most pigeon fanciers select on the basis of performance and forget that other major factors to consider might include features such as resistance to diseases. For example, respiratory problems are common during the racing season, and it appears that heredity partially determines resistance. Thus, the veterinarian should play a role in establishing selection criteria.

It is critically important to understand that there is a difference in genetic susceptibility among different pigeons. Selecting pigeons that are not clinically affected by a disease outbreak helps increase disease resistance in the future. This is the principle of "survival of the fittest". During the first 10 weeks, 25 to 30% of the young birds should be culled. An average of an additional 60% will be culled or lost over the next 3 years.

CRITERIA FOR SELECTION OF **BREEDERS**

A winning racing pigeon is not necessarily the best choice for breeding. Similarly, the best breeding bird may not always have a good racing record.

Theoretically, the best performing racing pigeons are the result of cross-breedings. One chooses a bird from a certain line based on race performance and breeds it to a bird that is genetically predisposed to disease resistance.

Offspring from such crossings are generally stronger and more viable but may not themselves make the best breeding pigeons (Figs 37.2a,b).

The quality of the breeding pigeon is determined by the achievements of its youngsters. There are several important qualities to select for in young birds. The birds should be visually healthy and strong and prove resistant to contagious diseases. Vigor, personality and intelligence are equally important. Birds should be creative in interacting with the rest of the flock, as successful cohabitation is required. Well-developed orientation skills are vitally important in gauging a pigeon's winning potential. Pigeons should be able to discern the most efficient route to return home without delay.

These criteria are applied at the earliest age, starting with eggs. Eggs that develop slowly and squabs that hatch late should be culled. The growth, development and feather quality are early characteristics that can be used to evaluate young pigeons. Physical abnormalities or delay in physical development are reasons to cull a bird.

Squabs should be able to fly by the age of 5 weeks. When youngsters start to fly around the loft, it is important to observe flight differences. The fancier should keep notes and compare observations among individual pigeons. Differences also can be noticed among youngsters during weaning. Ideally, a pigeon will find the water supply and start eating and drinking without any hesitation. It is not a good sign when a fledgling is slow to learn. Similarly, when it comes to finding a place to perch in the loft, which bird gets the most preferred spots? The ones that are chased away from the food source or ideal perches should be culled.

There will frequently be young pigeons that have a wet eye, a brown cere or abnormal feces. Even if these

Fig 37.2a | A typical breeding facility

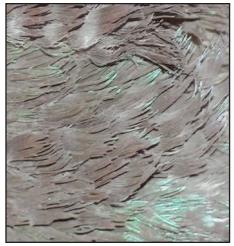

Fig 37.4 | Contour feathers are missing the proper structure to keep them smooth, and the normal shiny color has been lost. (Further examples showing lack of condition).

pigeons recover quickly, they should be culled. Culled birds should be recorded in the parents' records so improved matings can be undertaken in the future.

Criteria For Selection Of Birds To Race

The fancier's selection criteria for choosing birds to race often determines the success of his program. The author's current advice is to race a maximum of 50% of the available pigeons per race. When there is illness or other problems, racing a smaller percentage is advised. The decision to race an individual pigeon should be based on the condition of the bird, not on its previous performances. A decision so based can prevent the loss of good pigeons from over or misuse (Figs 37.3, 37.4). There are only a few very good pigeons. To race those pigeons in their prime is the goal, and this is more important than winning a particular race.

To judge the success of a selection program, the fancier should answer these questions: Is the percentage of the pigeons winning points in races increasing? Are there

fewer disease problems, especially during the racing season? Are there fewer birds lost at the end of races? Has the profit increased?

If the answers are negative, then the pigeons may not be in the best physical condition (Fig 37.5). Birds that are under-conditioned not only perform poorly, they do not have enough resistance to infection during transport. Such birds commonly have subclinical problems, especially respiratory disease (see Respiratory Problems, below). An opportune time to evaluate pigeons is immediately after their return from a race. A bird's recovery speed and any problems seen immediately after a race should be documented.

FANCIER'S COMMITMENT TO QUALITY

Year after year, champions come from lofts where the owners are committed to selecting quality birds. Good fanciers plan the purchase of new pigeons based on characteristics that will improve the flock rather than

Fig 37.5 | A section of this feather's vane is defective following a molt, supporting the evaluation of lack of proper condition.

Fig 37.6 | A pigeon loft, displays adequate but not excessive amounts of glass.

purchasing a new bird that has won a certain race. Old breeding stock should be kept pure to conserve good qualities in case cross-breedings do not work out as planned. While infectious diseases are still present and do spread among most of the lofts during the racing season, this commitment to quality ensures that infectious diseases generally don't play a major role in ideal lofts. On the other hand, an outbreak of herpesvirus infection can be devastating to young pigeons under any situation.

Fanciers should be educated on establishing high quality standards in their loft as well as their birds. They then can base husbandry decisions on logic, not on what other fanciers tell them. For example, in the past, a fancier often made the decision to put more glass in the loft roof, because everyone was putting glass in their roofs. The increased level of light was perceived by many to be advantageous, especially in the early months of the year. However, many fanciers did not think about the disadvantages. More glass resulted in greater temperature fluctuations. The excess glass promoted excess humidity in cool months, while it led to the loft becoming too hot and dry in the summer.

THE LOFT

Climate in the Loft

The loft's climate should be warm, dry and without draft (Fig 37.6). The environment of the pigeon house must be constantly monitored because temperature and humidity fluctuate with changes in the weather, as well as between day and night. A common error during cold, wet weather is to allow too much ventilation, which leads to a house colder on the inside than out. Instead, ventilation should be reduced and supplemental heat added. At the beginning of the season, the loft temperature should be at least 12° to 13° C (53-55° F) during the night. The humidity should not be over 70%.

During warm, dry periods, many pigeon houses are insufficiently ventilated, becoming hot and dusty and creating respiratory signs that fail to respond to any medication. The temperature should not be over 28° C (82° F). Otherwise, pigeons will start drinking more and eating less, which has a negative influence on their general condition. For example, this causes wetter droppings, which can incubate bacteria, fungus and yeast. The short-term instillation of smoke into the compartment during construction allows airflow to be visualized. The air inflow should enter above the level of the pigeons and exit out the roof.

The quality of pigeon houses is highly variable. During inspection, a check list will aid in identifying problems and making suggestions to correct these areas in the facility (eg, insulation materials used, ventilation errors).

The Number of Pigeons in the Loft

Overcrowding is an important cause of a poor loft environment (Fig 37.7). Crowding promotes feather dust, wet feces and excess moisture in expired air. Space is another consideration, as each pigeon needs its own space and territory. When birds are constantly competing for space, the number of birds is too high. Males are more competitive, so there should be fewer cocks than hens or chicks per cubic meter. When young pigeons reach 7 to 8 weeks of age, they begin to compete in the pecking order.

Over the past 10 years, the tendency of many fanciers has been to develop larger flocks each year, despite the fact that their facilities are not designed for expansion (Fig 37.8). Pigeon fanciers do not improve performance of the racing flock by simply producing more birds. Too many pigeons in improper facilities creates stress, increases dust, and, therefore, increases susceptibility to respiratory and other disease.

Fig 37.7 | A pigeon loft with a crowded outdoor flight cage creates an undesirable stressful situation.

Fig 37.8 | A youngster was mutilated as a result of overpopulation and stress.

Loft Space Guidelines

To avoid the problems of overcrowding, each loft should contain a maximum of two young pigeons, two adult females and one adult male per cubic meter. Therefore, in a loft of $2 \times 2 \times 2$ meters (8 cubic meters), there can be 16 young pigeons, 16 adult females and 8 adult males. Other recommendations suggest a maximum population density of half this number per unit space. During fledging, some overpopulation is acceptable because of the better climatic conditions in the early months of the year, including low temperature and high humidity. Overpopulation is very unfavorable during the racing season (ie, high temperature, low humidity), so a major cull must occur just prior to the racing season.

Separating Groups by Age

The adverse effects of housing birds of different ages together are well-known in the poultry industry. The same effects are seen in mixed-age groups of racing pigeons. By advancing the breeding season and breeding the same stock several times each year, many fanciers are creating and maintaining several different age groups within a flock. This is acceptable if the facility has been designed to accommodate multiple age groups.

The goal is to breed enough young pigeons so the fancier has the opportunity during the first 2 to 3 months to select the pigeons that exhibit the desired qualities, culling the balance to prevent overcrowding and avoiding the pitfalls such as stress and disease that come with keeping too great a number of individuals.

Veterinary Support

The aims of veterinary support are to ensure a healthy flock, to minimize the losses and to maximize success during the racing seasons.

PREVENTIVE MEASURES

Proper husbandry practices should be followed at all times. This includes areas both in and around the loft.

Monitoring Procedures

Particular attention must be paid to general body condition, molting or feather disturbances, signs of *Salmonella* spp., ectoparasites and endoparasites that may be present in the feces. A swab from the crop and/or cloaca should be obtained for cytology and Gram's stains and cultures if disease is suspected in a bird. Necropsies of poor performers or birds showing signs of disease can be important for monitoring the disease status of the flock.

Vaccinations

Routine vaccinations are imperative. Regulations regarding these may vary among countries. Paramyxovirus vaccine (Fig 37.9) should be given after 3 weeks of age and thereafter once a year about 3 weeks before breeding. Poxvirus vaccine should be given after 5 weeks of age and thereafter once a year at least 3 weeks before racing season. Salmonella vaccine is given after 5 weeks of age, then twice at 2-week intervals and 3 weeks before breeding.

Preventive Medications

Trichomoniasis (Fig 37.10) is one the most common infectious diseases among racing pigeons in the Netherlands. Trichomoniasis causes an erosion of the pharnygeal mucosa and increases susceptibility to other infectious agents (Fig 37.11). Hexamitiasis is also common.

Examination of young pigeons at the time of vaccination against paramyxovirus has shown that 35 to 40% of these birds, which show no clinical signs, are infected with

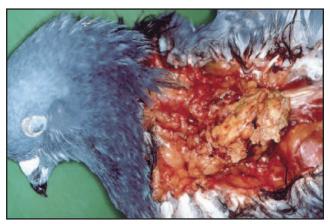

Fig 37.9 | Granuloma formation as a result of a vaccine reaction after using an oil-based paramyxovirus vaccine.

Fig 37.11 | Clinical signs of a combined infection with herpesvirus and trichomoniasis.

trichomonads. When clinical signs of respiratory disease are present, this percentage is much higher.

To control trichomoniasis, breeding pigeons should be treated when they are incubating their eggs. The offspring should then be treated at 5 weeks of age. Treatment consists of ronidazole once daily for 6 days and repeated for 3 to 4 days every 3 weeks. During the racing season, the pigeons should be treated every weekend upon their return from a race.

Medications should play only a minor role in the management of diseases in a loft. Use of medication should be based on a confirmed diagnoses. Refer to the literature for a more detailed discussion of medications and specifics on diseases. ¹² Unfortunately, European fanciers are encouraged to overuse medications. Companies that sell medicaments frequently advertise their products in publications designed for pigeon fanciers. Treatment for coccidiosis or other endoparasites and Salmonellosis should only be performed when these conditions have been diagnosed. A common misconception among fanciers is that these treatments will improve racing performance.

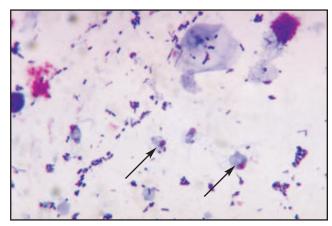

Fig 37.10 | Stained slide preparation of trichomoniasis (arrows).

The dosage of any medication is based on body weight. In general, 20 pigeons drink about 1 L of water per day, but intake can vary. Medications may also be administered in the food. A small amount of yogurt may be used as a vehicle in which to suspend medication that will adhere to the food.

The Presence of Escherichia coli (E. coli)

The presence of *E. coli* is considered a normal inhabitant of pigeons' intestinal flora. When *E. coli* is cultured at necropsy, it is important to look for concurrent viral diseases, especially circovirus, herpesvirus and adenovirus. Many fanciers will request bacterial cultures of sick or dead birds, and *E. coli* is frequently isolated. The fancier may mistakenly assume that the *E. coli* is the primary pathogen. Antibiotics sold over the counter are then administered to these birds. In the face of a viral infection, these antibiotics may not only be ineffective, but may also destroy the natural intestinal flora.

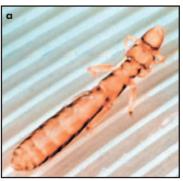

Veterinary Inspection of the Loft

The quality of veterinary support depends on the experience and knowledge of the veterinarian. The flock is considered the patient. Prevention is the creed. The veterinarian and the fancier should base their relationship on mutual respect and trust. The veterinarian's physically visiting the pigeon loft is an important part of the veterinary program.

When evaluating the loft, the veterinarian should note the physical facilities, including the direction the loft faces (preferably southeast); what materials were used for construction, insulation and roofing; the size of each loft; the amount of glass in front and on the roof; and what type of ventilation system is in use. He or she should note any trees, bushes, fences and buildings around the facility and evaluate them for safety and appropriateness (eg, ensure that there are no toxic plant materials or fencing that could prove harmful).

Fig 37.12 | Feather/quill mites.

Figs 37.13a | The slender pigeon louse, which can be considered harmless in small numbers, is a sign of poor health in large numbers.

Figs 37.13b | The small pigeon louse, which can cause much distress, is often found around the neck feathers and uropygial gland areas.

Fig 37.14 | Feces in the morning without distress at night.

Fig 37.15 | Feces in the morning as the result of distress at night because of mites and lice.

In evaluating the fancier's parasite control, the veterinarian should perform a thorough inspection of the birds for ectoparasites (Figs 37.12, 37.13a,b). Fecal examinations should be performed for endoparasites. Examining the cleanliness of the loft in general (Figs 37.14, 37.15), and the food and water sources in particular, is important for control of both endoparasites and potentially infectious microorganisms.

During this inspection, the veterinarian can verify that the population density and age separation criteria are appropriate, as well as noting and discussing nutrition, hygiene and other husbandry concerns that are significant.

Contagious Diseases

Contagious diseases are common, especially during the racing season. As discussed previously, preventing contagious diseases in racing pigeons is impossible (Fig 37.16). As a result, one must consider an individual flock as part of the whole pigeon population in the racing area and even as part of the whole racing pigeon sport, because birds travel between countries.

PREDISPOSING FACTORS THAT DETERMINE THE PATHOGENICITY OF A DISEASE

While it may not be possible to avoid all contagious infections in racing pigeons, there are many factors that influence the severity and scope of disease. Healthy, wellmaintained birds will suffer lower morbidity and mortality than immune compromised birds. Some factors that increase the pathogenicity of opportunistic diseases include: malnutrition, overpopulation (birds lower on the pecking order are more susceptible), suboptimal climate conditions within the loft, combining different age groups in the same loft, adding new pigeons to the flock, stressful situations within the flock, and racing birds that are not in proper condition. Diseases and vectors such as salmonellosis, trichomoniasis, heximitasis, mites, lice and endoparasites, can be immunosuppressive and increase morbidity and mortality of contagious diseases.

INFECTIOUS DISEASES AND **PARASITES**

While the fancier and veterinarian must be vigilant for a wide range of possible debilitating afflictions, some are more prevalent than others. The main infectious illnesses of racing pigeons include: viral diseases, chlamydophilosis

Fig 37.16 | Release of pigeons from the transport trucks to start a race.

Fig 37.17 | Green-yellow urine is often a first sign of adenovirus and/or herpesvirus infection.

Fig 37.18 | The death of youngsters within 1 day can be associated with circovirus or salmonellosis.

and parasitic diseases such as lice, mites, roundworms (Ascaridia, Capillaria), tapeworms, coccidia, Hexamita spp., trichomonads and trematodes. Additionally, birds may contract combined infections, known as "ornithosis complex", of the upper respiratory tract.12

VIRAL DISEASES

In most viral outbreaks, an otherwise healthy flock that is properly managed will have only a few birds sick and only a small percentage will die.12

Paramyxovirus and Poxvirus

Vaccines are available for annual protection against paramyxovirus and poxvirus in racing pigeons. By law, in Europe, pigeon fanciers must vaccinate their pigeons against paramyxovirus. There is evidence that pigeon paramyxovirus and the paramyxovirus that causes Newcastle disease in poultry are distinct. Poxvirus infection is transmitted by mosquitoes. During an outbreak, do not allow the pigeons to bathe. The ideal environment would include higher-than-normal temperatures, good ventilation and controlled humidity. Disinfection of the pigeon loft is important when a viral infection is suspected. It also is essential that all aspects of management and husbandry be evaluated and corrected if necessary.

Adenovirus

Adenovirus type 1 is especially common in young pigeons. Adenovirus type 2 is seen mainly in older pigeons, causing acute hepatitis and acute death. Pigeons that appeared to be healthy at the time of putting them in the baskets for a race can be dead on arrival at the race venue. Clinical signs of an adenovirus outbreak include reduced appetite, excessive drinking, regurgitation, loose voluminous feces, abnormal urine (yellow to green instead of white) (Fig 37.17), weight loss and acute death.

Herpesvirus

Clinical signs may include epiphora, rhinorrhea and diphtheric plaques in the mouth, throat and/or trachea similar to those seen with trichomoniasis or poxvirus. Anorexia, polydipsia and yellow-green urates may be present due to hepatic involvement. Herpesvirus can also cause central nervous system signs, such as paresis and paralysis. Differential diagnoses for the encephalitic form include paramyxovirus, salmonella, intoxications and trauma. A definitive diagnosis is made post-mortem via histopathology and/or viral culture.

Circovirus

First reported in 1990 in California, circovirus also has been found in Europe since 1995. The main characteristics are juvenile mortality and multiple secondary infections (Fig 37.18). Outbreaks of other infectious diseases are common because of the immunosuppression caused by circovirus. Anemia and paralysis may also be seen, as well as feather abnormalities similar to those seen in affected psittacines.

Pigeons infected with circovirus may not respond to a vaccination against paramyxovirus, poxvirus or salmonella, resulting in serious consequences. When pigeons vaccinated against paramyxovirus develop the disease, the legislation in Europe requires that all pigeons in close contact with affected birds be euthanized.

The most important tool for diagnosing circovirus is to submit tissues of infected organs for histopathologic examination. The bursa of Fabricius is a target organ in birds less than 6 weeks of age. In Belgium, there is a concerted effort underway to create a special pigeon circovirus PCR test.

Management of a Viral Disease Outbreak

Diseased pigeons must be culled from the loft as soon as clinical signs are noted. It is important to realize that

asymptomatic pigeons may still be infected. Not every pigeon gets sick or dies when infected with a contagious viral disease. When faced with an outbreak of paramyxovirus or poxvirus, immediate vaccination, using precautions to prevent further spread of disease, is imperative. Sick pigeons must be examined for the presence of other infectious diseases. Endoparasites and/or salmonella often need to be addressed. Antibiotics should not be used unless there is a confirmed bacterial infection. Reduce the number of young pigeons to a maximum of two per cubic meter.

To support recovery of the pigeons a combination of amino acids, lactobacillus, minerals, electrolytes and vitamins should be provided in the food. Add apple cider vinegar or citric acid (1 g/L) to the drinking water to decrease gastrointestinal pH. Alternating the administration of echinacea and green tea may decrease the incidence of secondary bacterial and yeast infections. Increased fresh air ventilation will decrease the concentration of viruses and aerosolized irritants.

RESPIRATORY PROBLEMS

Respiratory problems are among the more common reasons for poor racing performance and are generally caused by a combination of environmental factors and microbial agents. Pigeons may be subclinical but demonstrate diminished performance. A thorough examination may reveal conjunctivitis, dacrocystitis and/or pharyngitis. The breathing sounds of a normal pigeon, like those of other birds, should be inaudible even when the bird is held to the ear or auscultated.

Clinical Signs Associated with Mild Upper **Respiratory Problems**

The fancier should always be alert to clinical signs that can signal respiratory problems in the flock. Some of the more easily noticed signs may include "swollen head" due to the feathers being more erect, especially around the ears; similarly, the feathers around the head and neck may no longer be smooth, but become rough and dull. The ceres may no longer be dry with the normal white collection of powder down, but instead are a bit darker or even grayish. Additional clinical signs include epiphora, head shaking and scratching, sneezing and dyspnea. The nictitating membrane is often inflamed and swollen and remains extended; fanciers call it "the film". The bird may exhibit frequent swallowing and tongue movement. The mucous membranes in the pharynx and esophagus become swollen, and often the choanal slit is closed. Mucus is often visible around the glottis and may become viscous and whitish. The choanal papillae may change in shape and, in more chronic cases, even disappear.

Fig 37.19 | Mild respiratory problems may show only a very subtle dampness around the naris.

Fig 37.20 | Severe respiratory problems including conjunctivitis.

Clinical signs can be very subtle (Fig 37.19), which is why most pigeon fanciers do not suspect an infectious disease even when performance is disappointing. Poor race finishers should be examined by a veterinarian in order to detect the more subtle clinical signs.

Clinical Signs Associated with Severe Upper **Respiratory Problems**

Severe upper respiratory clinical signs are more readily noted and can include a dirty, wet, discolored cere; conjunctivitis with discoloration of the eyelids; wet areas on the shoulder or back feathers from eye wiping; and respiratory congestion (Fig 37.20). The sounds may be dry or moist. In severe cases where a tracheitis or other deeper respiratory problem is involved, the pigeon may be gasping for air with an open beak and have exaggerated abdominal and tail movements. Yellowish flakes may be observed on the mucous membranes of the oropharynx and tongue and in the trachea. These may be combined with diphtheritic membranes.

Infectious agents that may be involved in respiratory diseases of pigeons include pigeon herpesvirus, pigeon poxvirus, circovirus, Chlamydophila psittaci, Trichomonas sp., E. coli, Hemophilus spp. and Mycoplasma spp.

Differential Diagnoses for Respiratory Diseases

Poorly performing birds should be thoroughly examined. In making a list of differential diagnoses, as in all birds, many other disease conditions can present as respiratory distress, including egg binding, serositis, tumors, cysts, severe infestation with worms or coccida, cardiovascular disease and anemia. The infectious agents previously mentioned must be considered, in addition to less commonly occurring mycotic infections. Husbandry, including air quality and ventilation, may also be contributory. Inhalation of toxic fumes may also cause upper and or lower respiratory signs (Table 37.1).

In practice, one is often contending with a combination of these different agents and the complicating factors of dust, crowding and malnutrition.

Treatment of Respiratory Diseases

Treatment will depend upon the etiologic agents involved and may include vaccination, improved ventilation, dietary supplementation as previously outlined and antimicrobials when indicated.

Several affected individuals should be culled while implementation of prevention and treatment protocols are instituted for the remainder of the flock.

Table 37.1 | Differential Diagnoses Based on Clinical Signs

Clinical Signs	
Clinical Signs	Possible Causes
Loose, unformed feces (Fig 37.21)	 Endoparasites such as capillaria (Figs 37.22, 37.23), ascaridiasis (Fig 37.24), coccidiosis, hexamitiasis, trematodiasis, cestodiasis Bacterial infections including Salmonella typhimurium var. Copenhagen, Streptococcus bovis Viral infections including adenovirus, herpesvirus Intoxications, excessive ingestion of moss, sand Stress
Polyuria/polydipsia	Paramyxovirus Excessive dietary salt Intoxications Severe enteritis "Spraying" is a lay term that refers to polyuria and loose feces. It occurs in youngsters of about 10 days of age when the parents stop feeding crop milk. It also is seen during the stress of mating. Causes for such symptoms should be investigated
Respiratory problems	Improper loft conditions, eg, dust Unseasonal weather: too hot, too cold or wet Ornithose-complex Trichomoniasis (Fig 37.25), tumors (Fig 37.26) Herpesvirus Tracheitis/air sacculitis Obstructions within the trachea, syrinx (foreign body, mycoses, diphtheria) Pneumonia Ascites, egg binding, tumors, serositis, foreign body Circulation problems Obesity Excessively high temperature Bad general physical condition Overpopulation, stress Mixing different age groups
Diphtheric mucous membranes	Trichomoniasis Herpesvirus Poxvirus (Fig 37.27) There are many causes for these small yellow dots: E. coli (Fig 37.28) Candidiasis
Disturbance of equilibrium	Paramyxovirus Herpesvirus Salmonella Intoxication with substances such as dimetridazole, (Fig 37.32) or aminopyridine salt Encephalitis - trichomoniasis (Figs 37.29-37.30) Trauma Debilitation and emaciation-seen in birds returning from a race in inclement weather Anemia
Drooping wing, leg lameness	Salmonella Arthritis Myositis caused by Streptococcus bovis Muscle damage subsequent to trauma Fractures Joint luxations (Fig 37.33) Paralysis subsequent to egg laying (Fig 37.34) Paramyxovirus Leg swells under band (Fig 37.35)
Abnormal feathers	Malnutrition-for dietary considerations ¹² Can be caused by medication such as fenbendazole administered during the molting period Corticosteroids are reason for a delay in molting and typical growth lines (Fig 37.36) Paramyxovirus Circovirus Chronic diseases such as salmonellosis

Management of

Galliformes

GARY D. BUTCHER, BS, MS, DVM, PhD, Dipl ACPV

Fig 38.1 | In warm climates, game cocks are housed on "string walks". A leg leash, just long enough for the bird to reach a shelter but not to fight with other birds, allows group confinement. Fighting of cocks is considered inhumane and illegal in some countries; however, it is a part of the culture in others.

Members of the order Galliformes are found on every continent except Antarctica. The red junglefowl, common turkey and helmeted guinea fowl have been domesticated for centuries. Their descendants, through selective breeding, are of considerable economic importance today. Some varieties are very plentiful in the wild, while others like the Japanese quail (*Coturnix japonica*) and various pheasants are approaching a level of complete domestication.

Many Galliformes are commonly maintained as game and food (meat and/or eggs) birds. Some are stable in captivity under variable ambient conditions, easy to breed and inexpensive. Other species are from niches with specific environmental requirements and need specialized diets, humidity and temperature ranges to survive. Currently, commercial production of chickens and turkeys in the USA for food has surpassed that of the beef, pork and fish industries. In 1900, per capita consumption of chicken was 1 pound and had risen to 80 pounds by the year 2000!

In this chapter, "domestic fowl" means *Gallus gallus*, forma domestica (domestic form of the red junglefowl); "domestic turkey" is *Meleagris gallopavo*, forma domestica (domestic form of the common turkey) and "domestic guinea fowl" is *Numida meleagris*, forma domestica (domestic form of the helmeted guinea fowl) (Table 38.1).

Maintaining, breeding, treating or commercially dealing with gallinaceous birds may be regulated by laws that govern the protection of animals, property rights, exchange of goods, liability, epornitics, food for human consumption, hunting and (international) transport of animals. In the USA, voluntary federal and state programs such as the National Poultry Improvement Plan (NPIP) provide testing for specific diseases to facilitate interstate and international transport of fowl. Laws are

Table 38.1 | Families and Subfamilies of Gallinaceous Birds

Family (Subfamilies)	No. of Genera	No. of Species
Cracidae (cracids)	10	43
Megapodiidae (megapodes)	7	12
Phasianidae (phasianids)	70	203
Numidinae (guinea fowl)	4	6
Pavoninae (peafowl)	2	3
Meleagridinae (turkeys)	1	2
Argusianinae (peacock pheasants and argus pheasants)	3	8
Phasianinae (pheasants)	8	21
Lophophorinae (monals)	1	3
Pucrasiinae (koklass)	1	1
Ithagininae (blood pheasant)	1	1
Gallinae (junglefowl)	1	4
Tragopaninae (tragopans)	1	5
Galloperdicinae (spurfowl)	1	3
Ptilopachinae (stone partridge)	1	1
Perdicinae (partridges, snowcocks, francolins, Old World quail)	27	98
Odontophorinae (New World quail)	9	31
Tetraoninae (grouse)	9	16

presently in place and/or being considered in some states that would prevent the interstate or international transport of fowl for purposes of fighting (Fig 38.1).

Anatomy and Physiology

Considering the large number of birds in the order Galliformes, there are surprisingly minimal anatomic and physiologic differences as compared to other animal orders. Likely, the strict physical requirements for flight have limited variability. Several peculiarities should be discussed. In the circulatory system, for example, most gallinaceous birds have right and left internal carotid arteries; however, the megapodes have only the right internal carotid artery. The respiratory rates, heart rates and rectal temperatures of some gallinaceous birds are listed in Table 38.2 and are highly variable, depending on the metabolic rate and physiology of the specific bird.

INTEGUMENT

Many gallinaceous species develop a durable, vascularized thickening of the corium in the ventral thoracic region called a brooding spot. The feathers in this region are temporarily lost and body heat is transferred directly from the brooding bird to the eggs.

The preen gland in the domestic fowl consists of two bilaterally symmetric lobes, each with one secretory duct opening into the uropygial papillae. Some breeds of domestic fowl have two uropygial papillae. Tail-less breeds of the domestic fowl and the argus pheasants

Table 38.2 | Respiratory Rate, Heart Rate and Rectal Temperature of Selected Gallinaceous Birds

Bird Group	Respiratory Rate (per min)		
Domestic fowl	12-37	220-360	41.2
Domestic turkey	28-49	93-163	40.7
Pheasant	12-37	_	_
Bobwhite quail	_	_	44.0
Common quail	40-85	249-494	42.2

(*Argusianus argus*) have no preen gland. A brush-like feather tuft that absorbs secretions from the gland is present on the uropygial papillae. This feather tuft is absent in the megapodes.

Some gallinaceous birds have unique skin appendages. Junglefowl possess marked unpaired carneous combs consisting of a wide intermediate layer, which is formed of a fibrillar network filled with mucus-like substances that impact elastic stability of the comb. The strongly vascularized corium and the epidermis cover the intermediate layer. Feathers are present on the comb bonnet in some domestic fowl breeds. The paired wattles of the throat are similar in structure to the comb (Fig 38.2). Like the comb, the size of the wattles is influenced by hormones, and both are better developed in cocks than in hens. Paired cheek or earlobes are located ventral to the auditory canal and are of varying colors. It has been suggested that the color of the earlobe is related to the color of the eggshell in *Gallus gallus*.

The structure of the skin appendages on the head and neck of turkeys varies from those described in jungle-fowl. These appendages have no elastic intermediate layer but do have superficial, muscular and vascular layers. The dewlaps of turkeys are smooth, increase and decrease in size and can change color. Turkeys have a single snood on the forehead that can readily increase or decrease in length. Numerous red caruncles are located on the poorly feathered blue skin of the head. A beard consisting of tough, dark bristles is present at the border between the neck and chest. Turkey hens have more poorly developed skin appendages than cocks, and a beard is found occasionally in older hens, probably as a result of hormonal changes.

In New World quail (Odontophoridae), the edge of the lower bill is serrated or slightly jagged. An osseous process, which can be large in some species or subspecies, exists near the junction of the upper bill and cranium of helmeted guinea fowl and some cracids (Cracidae). This helmet consists of a cone of spongy bone covered by the corium and a keratinized epidermis. The wattles of the helmeted guinea fowl (*Numida meleagris*) are white to light blue and, like the helmet, are larger in cocks than in hens. Some other phasianids,

Fig 38.2 | Developed comb and wattles in the rooster (foreground) and hen are shown. The comb of the male is typically more prominent and brightly colored; in this case, it is cyanotic due to feed impaction of the crop.

some megapodes (Megapodiidae) and some cracids also possess ornamental appendages of the head and neck. In some species, these appendages are visible only during mating displays. Some breeds of the domestic fowl, some megapodes, some francolins, (Peliperdixidae), some tragopans (Tragopanidae) and some pheasants (Phasianidae) have completely featherless heads and necks, or featherless areas of the head or neck. Unfeathered areas of skin frequently are colored. Many grouse species (Bonasa spp.) have red-colored supraocular combs. These unfeathered regions become swollen during mating season.

The cocks of many gallinaceous birds have spurs, which are osseous eminences originating from the tarsometatarsus and are covered by keratinized epidermis. If spurs occur in hens, they are poorly developed and often have no osseous component. The cocks' spurs are frequently sharp and can easily injure rivals, hens, clients or veterinarians. Cracids and grouse do not have spurs. In the common pheasant, annual rings are formed in the epidermis at the base of the spurs and can be used to determine the minimum age of the bird.

Adaptations to Low Temperatures

The feet and toes of grouse are feathered. In ptarmigans (Lagopus spp.), even the plantar surface of the foot is covered with fur-like feathers. Long nails and keratinous pins on both sides of the digits facilitate locomotion on snow. Dense plumage and a thick layer of subcutaneous fatty tissue help protect against the cold. Hair-like feathers cover the nostrils. In ptarmigans, shivering for the active production of body heat starts only below -12° C.

Plumage

The chicks of all gallinaceous birds are nidifugous (can

ambulate and self feed) and hatch with a downy plumage. The deck feathers (tectrices), flight feathers (remiges) and tail feathers (rectrices) form the contour feathers of the plumage. The number of rectrices varies among different species: the domestic fowl has 7 pairs; the Bulwer's wattled pheasant has 12 to 16 pairs. Ornamental feathers can originate from different portions of the plumage, including tail coverts (peafowl), rectrices (many pheasants) and chin feathers (capercaillies). Birds that are indigenous to open terrain often have a patterned plumage that serves as camouflage. Some species like the golden pheasant show polychromatism of the plumage.

Dark periorbital feathers hide the eyes of many gallinaceous birds. Attempting to escape from predators by running or flying in open terrain is a poor defense; thus, most ground-dwelling gallinaceous birds remain immobile when predators approach, and flee only as a lastditch effort to escape.

Gallinaceous birds generally have well-developed afterfeathers (hypopennae). In some cracids, the vanes of the first primaries are curved and narrow, which, when a bird flies, produce a unique sound that is used to mark its territory.

Most gallinaceous birds molt naturally once a year, generally after the breeding season. Gallinaceous birds retain their ability to fly during a molt. The secondaries are molted in a divergent pattern from an inner starting point. The rectrices are molted randomly. The willow ptarmigan lives in a subarctic-type habitat and molts three times a year in order to adapt to color changes in the environment, with the winter plumage being mainly white. Some grouse (capercaillies and ptarmigans) even molt the horny sheath (rhamphotheca) of the bill (in small pieces) after the breeding season. Ptarmigans also replace their nails. Molting of commercial chickens is often done on a scheduled basis to improve the level of egg production and quality of the eggshell.

Some birds (notably grouse [Tetraoninae], pigeons [Columbidae]) undergo a stress-induced physiologic response when attacked by predators, which results in release of the feathers (the shock or fright molt). The predator or handler is left with a collection of feathers and the bird escapes.

Gallinaceous birds normally fly at a low level, have a high-frequency wing flap and tire quite rapidly. Their flight is often limited to gliding for short distances. Some species lead a nomadic life. Birds that dwell in high mountainous regions in the summer usually move to lower altitudes in the winter. The only true migratory gallinaceous birds are the common quail (Coturnix

coturnix) and the Japanese quail. Some gallinaceous birds move by running, which is assisted by quick flapping of the wings. A normal cruising speed for the common pheasant would be 33 km/h (20.5 mph), while the common turkey cruises through the forest at 24 km/h (15 mph). The nidifugous chicks of the gallinaceous birds are able to fly shortly after hatching. The chicks of the phasianids first attempt to fly at the age of 10 to 16 days, and the cracid chicks start to fly 3 to 4 days after hatching. Megapode chicks, which are not tended by their parents, are able to fly short distances just after hatching.

LOCOMOTOR SYSTEM

The furcula (wishbone) of the domestic fowl is V-shaped and has a ventral process. In the crested and plumed guinea fowl (Numidinae), an indentation exists at the junction of the two clavicles. This indentation holds the U-shaped loop of the elongated trachea. The medial notch of the sternum extends far cranially, and fibrous membranes connect the lateral and medial notches. In this region, the sternum does not protect the liver, and injections, abdominocentesis or handling procedures must be carefully performed.

The ground-dwelling phasianids generally have a long femur, tibiotarsus and tarsometatarsus to facilitate ambulation, while the tree-dwelling cracids have shorter tarsometatarsi. The legs of all gallinaceous birds are well muscled. Cracids are active climbers, and other gallinaceous birds need strong feet and legs to scratch the ground in search of food. The toes of cracids and megapodes are on the same plane, whereas the first toe of the phasianids originates more proximally than the other digits. The first digit of the gallinaceous birds is oriented mediocaudally and the three other digits are directed cranially. Some breeds of the domestic fowl have five digits, with the additional digit being located medial to the first.

RESPIRATORY SYSTEM

Desert-dwelling gallinaceous birds such as sand partridges (*Ammoperdix heyi*) possess well-developed salt glands situated in an osseous indentation above the eyes. This extrarenal excretory organ for salt empties through a duct into the nasal cavity.

The cocks or both genders of some gallinaceous birds have elongated tracheas. The additional length produces a U-shaped or circular loop in the trachea that lies between the skin and the muscle layer in the ventral thoracic or cranial abdominal region. In helmeted curassows, the loop extends to the cloaca, and in some other cracids, it extends to the caudal end of the sternum. Crested and plumed guinea fowl and the common

capercaillie also have elongated tracheas. Although the function of the loop is not fully understood, it may be involved in generating deep sounds.

The tracheobronchial syrinx of gallinaceous birds is a simple structure. The neopulmo, which is the phylogenetically younger portion of the lung, is well developed in Galliformes. A phylogenetic increase in the size of the neopulmo is accompanied by a decrease in the size of the caudal thoracic air sacs. The common turkey has a well-developed neopulmo and has no caudal thoracic air sacs. Four clavicular air sacs are recognized in gallinaceous embryos. In the common turkey, only two of the four clavicular air sacs merge with the unpaired cervical air sac, and two clavicular air sacs remain distinct. In other birds, all the embryonic clavicular air sacs merge into one. With these adaptations, the common turkey has only seven air sacs, while most gallinaceous birds have nine air sacs: the unpaired clavicular air sac, and the paired cervical, cranial thoracic, caudal thoracic and abdominal air sacs.

ALIMENTARY TRACT

Most gallinaceous birds have a pointed bill (rostrum) that is used to pick up food. In grouse, the bill is stronger and is used for cutting tough vegetable matter. In gallinaceous birds, the cere is usually limited to the base of the upper bill; however, in cracids, two-thirds of the bill is covered by the cere.

The tongue of gallinaceous birds is shaped like an acute triangle, is stabilized by a bone and has no intrinsic musculature. Most gallinaceous birds have a crop. This esophageal diverticulum is missing in small cracids and snowcocks, and in its place is a slight bulge in the diameter of the esophagus or only an increased stretchability of the esophagus. The sage grouse (*Centocercus minimus*) and some other North American grouse (*Artemisia* spp.) use a diverticulum in the middle part of the esophagus for territorial display and not for the storage of food. During display, the "inflatable esophageal air sacs" are inflated to expose featherless, brightly colored skin. The organ also may play a part in amplifying the voice.

The ventriculus and its associated musculature are well developed in most gallinaceous birds. Grouse and snow-cocks (*Tetraogallus bimalayensis*), which eat extremely rough food, possess the most heavily muscled ventriculi. The sage grouse, which feeds on soft food, has a thin-walled ventriculus.

The secretory ducts of the liver and the pancreas open into the duodenum. Gallinaceous birds have a gall bladder and two bile ducts. In the domestic fowl, the pancreas extends to the apex of the duodenal loop and

generally has three secretory ducts. The largest pancreas is found in gallinaceous birds that feed on grain.

All gallinaceous birds have well-developed ceca. Peristaltic movements of the small intestine and antiperistaltic movements of the rectum transport fluid and small food particles into the cecal lumen. The contents of the ceca are dark-colored and have a sticky consistency. The size of the ceca will increase or decrease, depending on the amount of crude fiber in the diet. In some species, bacterial digestion of cellulose occurs in the ceca. Species like grouse and snow cocks, which feed on foods with high amounts of crude fiber, have particularly well-developed ceca.

The cecal flora probably plays an important role in the synthesis of vitamins and the metabolism of nitrogen. Uric acid that enters the cloaca is transported into the ceca by antiperistaltic movements of the rectum and is used for the synthesis of amino acids produced by bacteria and available to the bird. The ceca are usually emptied once a day, typically in the morning.

URINARY AND REPRODUCTIVE SYSTEMS

The testicles are generally yellowish or white but can be pigmented in some species like the common capercaillie or in some breeds of the domestic fowl. The testicles enlarge during the breeding season. Fertile semen is not produced between breeding seasons. The ductus deferens and, in some species, an enlarged area of the caudal ductus deferens serve as reservoirs for the storage of semen. Gallinaceous cocks have a non-erectile phallus.

Husbandry

Most gallinaceous birds are best maintained in combination indoor and outdoor aviaries and can live to 6 to 20 years, depending on the species (Table 38.3). In general, the available space should be as large as possible. In some countries, law stipulates the minimum areas.

A pair of pheasants can be maintained and bred in an aviary with a floor space 4 x 6 m with an additional 4-m² shelter. A common pheasant cock with five to six hens needs 30 to 38 m². An aviary for peafowl should be at least 3 m wide x 3 m deep x 3 m high. These species are best maintained in open-air enclosures or big gardens. One pair of bobwhite (*Colinus virginianus ridgwagi*) or California quail (*Callipepla californica*) needs a minimum of 1.5 m x 1.5 m floor space. For grouse, small aviaries 4 m deep x 8 m wide are recommended, because these birds may injure themselves if they fly into netting at the high speeds attained in larger flights.

Table 38.3 | Longevity of Selected Gallinaceous Birds

Bird	Years	
Peafowl	Approx. 20	
Bobwhite quail	Approx. 6	
Grouse	8-10	
Common pheasant	10-18	
Cracids	20+	

Fig 38.3 | A pheasant is provided with protection from the elements in an enclosure with a simple A-frame shelter at a popular zoological garden. Note the bent toes, a form of metabolic bone disease from malnutrition.

Many Galliformes prefer to roost in elevated positions, making the height of an aviary important. Shelters should be provided to protect birds from sun, wind and rain (Fig 38.3). Tropical or subtropical species maintained in cold climates require an indoor aviary or, if kept outdoors in winter, a heated shelter. The mesh size of netting should be small enough to prevent a bird from placing its head through the mesh, and preventing a predator from injuring or killing the bird. It also should prevent the smallest predators from entering the aviary. Some gallinaceous birds, especially the common pheasant and many quail,23 fly straight up when panicked. For this species, the top netting in an enclosure should be loose to provide some give and reduce the chances of head24 (scalping) and neck injuries. An opaque barrier can be placed at the back of the aviary, extending up to one-half of the height, to provide extra visual security for the birds.

Ground dwellers like some quail, partridges and francolins do not need elevated perches. Perches should be placed far enough from walls or wire netting to prevent the tail or wing feathers from contacting these surfaces. Peafowl, Reeve's pheasant (*Syrmaticus reevesii*), argus pheasants and Phoenix fowl (a strain of red junglefowl) require especially high perches placed 3 to 4 m above the ground to accommodate their long tail feathers.

Sharp corners should be avoided in designing the aviary. Curved corners or dense bushes planted in the corners reduce the possibility of trauma.

Shrubs also help to landscape an aviary and provide shelter for the birds; however, the aviary should not be over-planted. Too many plants will make an aviary difficult to clean. Natural turfs are attractive but are not recommended when keeping birds that are highly susceptible to infectious diseases. An aviary with a concrete floor that is covered with an exchangeable layer of sand meets the needs of sensitive species (like grouse or the cheer pheasant) and is better than natural soil. Plants may be grown in containers that are removed when the aviary needs cleaning.

Snowcocks need large rocks for perching and shaping their bills. Some species like monals, eared pheasants (Crossoptilon crossoptilon) and the cheer pheasant (Catreus wallichi) use their upper bill to search the soil for roots and insects. If these birds are maintained on artificial substrate, natural abrasion of the bill will not occur and manual trimming will be necessary. Gallinaceous birds do not bathe in water. Most gallinaceous birds like to take dust or sand baths. The placement of abrasive materials on the plumage may function to lightly abrade and polish the edges of the feathers and may help reduce the number of external parasites as long as the sand itself is not contaminated. Insect powders should be used only if they are known to be nontoxic for the species concerned and only if the birds do in fact have parasites. In the winter, willow ptarmigan bathe in the snow.

Various bird species should generally not be mixed in one aviary because of possible interspecific aggression and the potential transmission of infectious agents. If species are combined, it is best to mix birds that do not compete for the same food or biotope and have originated from the same geographic region.²⁵ Grounddwelling gallinaceous birds can be combined with bushor tree-living species like thrushes, babblers, starlings, bulbuls and doves (with the exception of the ground pigeon); however, mixing of species is not recommended. Predatory species, including birds that feed on eggs, should not be combined with gallinaceous birds.

Silver pheasant (Lophura nycthemera), eared pheasant (Crossoptilon auritum), golden pheasant (Chrysolophus pictus), Lady Amherst's pheasant (Chrysolophus amherstiae), Elliot's pheasant (Syrmaticus ellioti), and Indian peafowl can be maintained in open-air enclosures that are fenced but not covered. Birds in open-air enclosures must have sufficient hedges, bushes or trees for protection. Higher trees should be available for roosting. Fruit trees or oaks (some are poisonous) provide a food

source as well as cover. Clipping the wings before introducing it to new surroundings should reduce the flight capacity of a bird.

Losses to predators can occur in open-topped facilities, particularly with respect to chicks. Rare species should not be maintained in an open-topped enclosure. A breeder who uses open-topped enclosures should expect that the loss of a bird to a predator is the responsibility of the breeder and not the fault of the predator. Some gallinaceous birds are noisy, especially the Indian peafowl and guinea fowl during the breeding season, and should be maintained in secluded areas to avoid complaints from neighbors.

Nutrition

Many diseases and problems in captive Galliformes are directly or indirectly related to malnutrition. Breeders of gallinaceous birds should be aware of the natural foods consumed by any species maintained in captivity. Conclusive data on the nutritional demands (with respect to maximal egg or meat production and not for longevity and appearance) is available only for the domestic fowl, domestic turkey and the Japanese quail. Some information is available for the domestic guinea fowl and less has been determined for the common pheasant. All nutritional guidelines for other gallinaceous birds are based on experience.26 Special care must be exercised when feeding commercial turkey and/or chicken feeds. Levels of calcium, protein and energy vary considerably among the starter, grower, layer and finisher rations. As well, many commercial poultry feeds contain antibiotics and other drugs (anticoccidials) that may be harmful to some birds or other animals on the premises.

Generally, the protein requirement increases at the beginning of the mating season because of egg and semen production. After the breeding season, the amount of protein in the feed should be gradually reduced. With any change in the diet, the new food should be mixed slowly into the daily diet until the conversion is complete.

"EASY" BIRDS

Many gallinaceous birds are omnivorous. The nutritional requirements of common pheasant, golden pheasant, peafowl, guinea fowl, turkeys, partridges and New World quail are relatively easy to provide. Commercial diets for domestic fowl, domestic turkey, common pheasant and Japanese quail are available in many countries. Pellets designed for turkeys can be used in species without special requirements. Adding fresh green plants to the diet

provides the birds with nutritional diversity. Grass or corn silage also can be offered in small quantities. During the breeding season, the diet should contain 20 to 25% crude protein. Outside the breeding season, a maintenance diet containing less than 20% crude protein is best. Commercial diets for the domestic turkey are usually better suited for pheasants than diets developed for domestic fowl. Feeding is best accomplished by providing small portions of the diet several times a day in the non-breeding season and offering food ad libitum during the breeding season.

Most New World quail are primarily seed eaters and are easy to feed. Forest-adapted species may be largely insectivorous and have higher and more specific protein requirements in comparison to other gallinaceous birds. Cracids are mainly, but not exclusively, vegetarians. They can be sustained on pellets containing 21% crude protein supplemented with fruits but no grains. During the breeding season, they are fed soybean paste, chopped hard-cooked eggs, chopped meat or mealworms (larvae of the meal beetle) with calcium as a supplement. The primarily meat diet of these birds results in odiferous feces. Megapodes can be fed a commercial poultry diet.

Birds with a High Protein Requirement

Some gallinaceous birds like peacock pheasants (Polyplectron bialcaratum), argus pheasants and the roulroul (crested wood partridge) do best with high-protein diets. In addition to high-protein turkey or pheasant diets, adult peacock pheasants should be fed mealworms, chopped meat, fruits and a small quantity of grain. Green plants are rarely consumed by these species. The roulroul is fed a commercial soft feed for insectivorous birds, mixed with live insects, chopped hard-cooked eggs and chopped meat with calcium as a supplement.

"DIFFICULT" BIRDS

Some gallinaceous birds consume almost exclusively vegetable material. The koklass (Pucrasia marolapha), the blood pheasant (Ithaginis cruentus), snowcocks, tragopans and grouse are examples. Feeding these species with game bird pellets or, even worse, with commercial diets for domestic fowl and turkeys results in obesity, reduced fertility and imbalances in the intestinal microflora. These species should be maintained only where natural-type foods are available year-round. These gallinaceous birds should be fed large amounts of fresh vegetables. Pellets should be provided only in small quantities, if at all. Koklass naturally feed on ferns, grasses, leaves, mosses, buds and berries. In captivity they should be provided soft green plants, fruits and berries, and no grains. In the summer, grasses and lucerne (alfalfa) can be provided. Spinach, romaine lettuce and fresh, frozen vegetables can

be substituted in the winter months. Free-ranging blood pheasants feed on mosses, lichen, ferns, grass tips and conifer needle-buds. They browse constantly in planted aviaries. Their chicks feed on these plants immediately after hatching.

Tragopans consume oak trees, bamboo sprouts, grasses, mosses, oak nuts, berries and a few insects. In captivity, tragopans can be fed lucerne, grasses, cucumbers, apples and different kinds of berries. In the spring, summer and autumn, grouse feed on a variety of plants. In the winter, most grouse species are restricted to consuming one or a few plant species. During the winter season, the spruce grouse, capercaillies and other grouse species feed almost exclusively on conifer needles, the black grouse on birch buds, and ptarmigans on buds from different deciduous trees (birch, alder, willow).

Captive grouse should receive natural foods or at least large amounts of leaves, grass and berries supplemented with a limited quantity of pellets and grain. Capercaillies and ptarmigans require a diet high in crude fiber. Even with strict attention to the diet, the bacterial fecal flora in capercaillies in captivity is similar to the fecal flora of the domestic fowl and differs substantially from the fecal flora of free-ranging capercaillies. The tannin and essential oil content of natural food plants may support the growth of autochthonous intestinal flora in free-ranging grouse. In the sage grouse, leaves and sprouts of the North American big sagebrush are the sole winter food and the main portion of food in the summer.

Some commercial poultry diets contain coccidiostatic agents. Halofuginone is toxic for the common pheasant, guinea fowl and the common partridge. Monensin is toxic for guineafowl. The presence of antimicrobial agents can be life-threatening in species that depend on a functional cecal flora and fauna (eg, grouse) for proper digestion. In general, the effects of coccidiostats and other medical feed supplements on gallinaceous birds have not been sufficiently studied. It is safer to provide food without these potentially toxic supplements.

All gallinaceous birds should have access to grit, when not fed strictly an artificial diet. The grit container should be emptied and refilled regularly because birds select only stones that are suitable for their body mass. Pellets or complete rations have an adequate supply of calcium and should not be supplemented with lime or crushed shell. Fresh, clean water must be available at all times for all species.

CHICKS

During their first few weeks of life, free-ranging gallinaceous chicks feed mainly on live invertebrates like insects, larvae of insects, worms and snails in order to obtain the protein levels needed to sustain rapid growth. Starting at 5 to 6 weeks of age, the protein requirements begin to decrease and the intake of carbohydrates increases to meet energy requirements. By 6 months of age, most young gallinaceous birds have reached a mass equivalent to that of adults. The quantity of carbohydrates in the diet must then be reduced to prevent obesity.

Feed should be provided to newly hatched chicks on a large, flat plate on which they can move around and practice pecking. By 5 to 7 days of age, food can be offered in larger containers. The change from the plate to larger containers should occur by offering feed in both containers at the same time. Small chicks may drown in large water containers.²⁸ Reducing the drinker depth by placing stones or glass marbles in the container will reduce losses.

Chicks of unpretentious species (common pheasant, peafowl, guinea fowl) are initially fed a starter diet like turkey starter (28% crude protein) and are transferred to a lower protein diet like turkey grower (18-20% crude protein) from the eighth to eighteenth week of age.²⁹

Chicks of the vegetarian species are difficult to feed. It is best to provide these birds with foods that are similar to those eaten by their free-ranging counterparts. A diet composed of turkey starter mixed with mealworms, ant cocoons, chopped hard-cooked eggs, diced romaine lettuce, spinach, dandelion and other green plants is a viable substitute. In several species (some grouse), chicks obtain food by pecking at the ground and by cutting off parts of plants with the bill. In these species, it is important that chicks be provided intact plants that are placed in the ground or tied in bundles to facilitate natural food-gathering behavior. Chicks that are to be released into the wild must be introduced to their natural foods to prevent starvation. Perhaps chicks are imprinted with food shapes and colors, or at the least they learn what foods to consume from the hen.

The chicks of some gallinaceous birds will not pick downward in the first days of life. This is because peacock pheasants, crested argus, great argus and some other gallinaceous hens feed their chicks for several days after hatching. Argus pheasant chicks can be enticed to peck by offering live food (mealworms). Monal chicks fed mealworms will pick at their siblings' toes.

Reproduction

Some gallinaceous birds breed easily in captivity, while others rarely reproduce. Breeding failures are an indication that the birds are not provided a suitable environment or there may be medical problems with the individual birds.³⁰ Some pheasant and quail species are approaching a level of domestication that is advantageous for both the captive animal and the breeder. Comparatively, "semi-domesticated" animals are of no value if offspring are to be released to the wild with the intent of reintroducing genetic diversity into dwindling populations. Genetic selection and breeding to achieve color variants increase the expression of genetic abnormalities, semi-lethal factors and susceptibility to disease. The clutch size and incubation times for commonly maintained gallinaceous birds are listed in Table 38.4. Parameters for artificial incubation are listed in Table 38.5.

GENERAL CONSIDERATIONS

Gallinaceous birds to be used for breeding purposes should be introduced to each other before the breeding season in surroundings that are novel to both the males and females. The female should be introduced to the enclosure a few hours prior to the male. In some species, it is possible to keep several males together if there are no females present. If females are present, only one male should be housed in an aviary or in one compartment. In monogamous species, only a single pair should be housed together.²⁸

Males of some species are very aggressive. During the breeding season, they may attack other males, other bird species or even the keeper. Pursuit by the male and mock escape by the female is normal behavior in some species like eared pheasants and francolins. If there is insufficient space for the hen to escape, she may be injured or killed by the cock. Beak trimming or restricting the flight capabilities of the male can prevent injuries to the hen, but are inferior procedures to providing adequate space for a pair of birds to behave normally. Densely planted aviaries that provide a hen with areas to hide still may have inherent problems. Fiberglass panels leaned against the wall or concrete tubes provide similar protection and are easy to clean.

For species in which there are substantial differences in body size between the genders, aviaries can be designed to allow the hen to visit the cock when she wishes. Small holes just big enough for the hen are used to connect adjacent enclosures. This allows the hen to enter the cock's enclosure while preventing the cock from entering the hen's area. This is an effective method for breeding birds like the common capercaillie. In some species, the hen chooses the most attractive of several cocks and if only one cock is available, breeding may not occur if the hen does not like the cock. In some species, the visual or acoustic presence of other males is necessary to stimulate display and mating behavior.

Most gallinaceous birds incubate eggs on the ground and should be provided with flat trays containing moss, foliage or hay for nesting material. Tragopans, the Congo peafowl (Afropavo congosis), the bronze-tailed peacock pheasant (Pavo cristatus), the crested argus pheasant, the mikado pheasant (Syrmaticus mikado), the Salvadori's pheasant (Lophura inornata) and the cracids nest in trees. A box placed approximately 150 cm from the ground and filled with hay and foliage can be used as an artificial nest. A slanted limb should be provided for easy access to the nest. Nests of ground- and

tree-nesting birds should be inconspicuous to provide the pair with visual security, but should be placed such that the birds can easily look out.

Most gallinaceous birds are non-determinant layers and if the first clutch of eggs is removed, the hen will lay a second and sometimes a third clutch. Hatching is genetically determined and should not normally be assisted. Because gallinaceous chicks are nidifugous, the family can stay together only if all the chicks hatch at the same time. Synchronization of the hatch dates can occur by two mechanisms: 1) The hen does not incubate the

Table 38.5 | Parameters for Artificial Incubation of Some **Gallinaceous Birds**

	Incubation Chamber		Hatching	Chamber
Species	Temp. (°C)	Humidity (%)	Temp. (°C)	Humidity (%)
Common pheasant (Phasianus colchicus)	37.5	60	37	85
California quail (Callipepla californica)	38.5-39.0	50-60	_	80

Chukar partridge (Alectoris chukar)	37.5	65	37	85

clutch until the last egg has been laid, allowing the eggs to cool (which slows the process of embryogenesis); or 2) The chicks in a clutch synchronize hatching through audible signals. This latter process occurs in species like the Japanese quail. When sounds are heard from other eggs, the chicks increase the speed of hatching. When no sounds are heard from other eggs, the most developed chicks reduce their speed of hatching. Most gallinaceous chicks are independent by 3 months of age. The exception is the megapode chick, which is independent immediately after hatching.

Foster Breeding

The hens of some gallinaceous birds are unreliable brooders in captivity. Cracid, common pheasant and nearly all species of New World quail hens are not reliable brooders in captivity. These hens can be encouraged to produce two or three clutches per year instead of one by using foster parents or an incubator for hatching eggs. Chinese silk fowl (Bambusicola thoracica) and bantams make excellent foster parents (Fig 38.4). Domestic turkey hens can be used to incubate the eggs of larger gallinaceous birds. Small and fragile eggs should be placed under golden pheasant hens, which are cautious brooders and excellent care providers. During the last week of incubation, the eggs of tropical birds being raised in dry climates should be moistened with a clean mister once a day. After hatching, the hens and chicks can be placed in a small enclosure that is moveable and can be placed on fresh grassy areas on a daily basis. Chicks are prone to chilling the first few days posthatch and must have supplemental body heat from the attending hen or a heat lamp where appropriate.

The disadvantages of foster parenting are as follows:

- Crushing of small, fragile eggs by heavy or clumsy adults
- Premature cessation of brooding if the natural incuba-

Fig 38.4 | The red junglefowl hen is commonly used by aviculturists to incubate the eggs of species that commonly abandon their eggs.

- tion period of the foster hen is shorter than the fostered eggs
- Trauma or death of the chicks if the hen recognizes them to be strange (this is a particular problem when behavioral incompatibilities exist between the hen and chicks)
- Transmission of infectious agents between hen and chicks
- Inappropriate imprinting

Placing the eggs in an incubator for the last third of the incubation period can reduce infanticide and disease transmission (this method is often used for grouse). A hen of the same species should rear chicks that are to be released into the wild.

For many pheasants, the percentage of carbon dioxide in the incubator must be increased up to approximately 1% (verified with a gas detector) during the last 2 days of incubation. This is achieved by reducing the intake of fresh air and serves to stimulate the hatching process. Chicks should be taken out of the incubator immediately after hatching.

SPECIFIC REPRODUCTIVE CHARACTERISTICS

Megapodes

Megapode eggs differ from those of other gallinaceous birds, owing to their uncommon brooding biology. The eggs are not incubated by the parents but by solar heat, fermentation heat or geothermal energy. One egg can reach a size of up to 17% of the hen's body mass. The eggs are thin shelled and contain a large yolk that is rich in lipids. Cocks or both sexes begin constructing an induction mound out of foliage and earth when the air temperature and atmospheric humidity reach a certain level. The hens lay their eggs every 2 to 3 days in previously prepared holes, which are quickly covered after oviposition. Eggs are deposited in a mound, with the pointed pole downward, and they are not turned during incubation. They do not have a fixed air chamber or chalaza.

The birds may determine the temperature of the mound, and perhaps other parameters, with the bill or tongue. The mean temperature in the incubation mound is around 34° C. The incubation mound is cooled when needed by scratching holes. This allows carbon dioxide to escape and oxygen to enter. The incubation period varies from 45 to 90 days, depending on the temperature in the mound. Brush turkey chicks leave the mound 24 to 30 hours after hatching. Normally, megapode chicks do not come into contact with their parents, which function only to care for the incubation mound. The chicks join their siblings that have hatched at around the same time. Megapodes are sexually mature by 1 year of age.

The Australian brush turkey (Alectura lathami) is easy to maintain and breed in captivity, and is the most common captive representative of the megapodes. This species is monogamous. In one breeding season, an Australian brush turkey hen lays about 25 to 30 eggs.

Cracids

Cracids are Central and South American species that are considered monogamous. The breeding season lasts from March until July. Most nests are well hidden in a fork or branch of a tree, but some species are groundnesters. Only the hen incubates the eggs. A clutch consists of two to three eggs, which are rough shelled with wide pores and a uniform white color. Newly hatched chicks are immediately able to climb trees. The family stays together until the next breeding season. Sexual maturity occurs by 2 years of age.

Turkeys

The common turkey is polygamous. Behavior of freeranging birds is dramatically different from that of domesticated breeds. The brain volume of domesticated turkeys is 3% smaller (brain:body weight ratio) than that of their wild-type conspecifics. The nest is formed of a flat depression in the soil and may be padded with leaves, grass or twigs. The chicks are able to fly at 2 weeks of age. Several hens, together with their offspring, typically associate in a flock in the winter. The young birds leave their mother before the next breeding season. Young turkeys are sexually mature at 2 years of age.

New World Quail

New World quail are monogamous. Both parents participate in building the nest and brooding the chicks. Young birds are sexually mature by 1 year of age, in some species even earlier. Outside the breeding season, the

gregarious New World quail live together in large family groups (coveys). At the beginning of the breeding season, the older cocks become very aggressive toward young cocks. Captive bobwhite quail have become polygamous and it is possible to keep one cock with two hens, indicating the effects of domestication.

Grouse

Some grouse species like ptarmigan, ruffed grouse, hazel hen (Tetrastes bonasia), spruce grouse (Falcipennis canadensis) and blue grouse (Dendragapus obscurus) are monogamous. In these species, cocks should not be allowed to see or hear other cocks. Hazel hen males may attack the female if a rival can be heard but not seen. Other grouse species are polygamous. In these species, the hen chooses one cock from a group of displaying males. One cock may be chosen to mate with several hens. Hens in captivity breed best when allowed to choose between two or more cocks. The cocks, which are housed in different compartments of an aviary, may see and hear each other if there are enough hiding places for the hens. In most grouse only the hen provides chick care. The chicks of different species can be distinguished by the varying color patterns on the head and back plumage. Most grouse are sexually mature at 1 year of age. Crossbreeding between different genera and species occurs in free-ranging birds. Similarities in the appearance and display behavior of hens seem to induce cocks to crossbreed. Hens will choose cocks of another species if a representative of their own species is not available.

Peafowl

The Congo peafowl is monogamous. The nest is always built in a tree. Both parents care for the chicks. The Indian (Pavo cristatus) and the green peafowl (Pavo muticus) are polygamous. In captivity, it is possible to keep one cock with four to five hens. The hens care for the clutch and the chicks, which mature slowly. Hens reach sexual maturity in the second year and cocks in the third year of life. The green peafowl is more aggressive than the Indian peafowl, but has a more pleasant call.

Pheasant

Most pheasant species are polygamous. One common pheasant cock can be kept with five to six hens (Fig 38.5). The hens make poor care providers in captivity. They tend to be indiscriminate in the placement of eggs and will not incubate the eggs. Young common pheasants are sexually mature at 1 year of age. Free-ranging golden pheasants are monogamous, but in captivity one cock can be kept with three to four hens. The hens are exceptional care providers and defend their chicks. Young golden pheasant hens are sexually mature within 1 year, cocks within 2 years. Lady Amherst's pheasant

Fig 38.5 | A male Reeves pheasant has worn a path in its aviary in an attempt to find mates or compete with other males.

cocks and hens can be aggressive during the breeding season. Only a few of the birds found in captivity are purebred. Both male and female argus pheasants, peacock pheasants and the copper pheasant establish and defend their own territories. Males should be introduced to females for only a short time during the breeding season to prevent aggressive behavior and traumatic injuries to both genders.

Junglefowl and Domestic Fowl

Junglefowl can either be monogamous or polygamous. The hens can breed year-round, but the main breeding season is from February to May in the northern hemisphere. A red junglefowl cock can be maintained with three to four hens. The young birds are independent at an age of 4 months and sexually mature after the first year. Many domestic fowl breeds have lost much of their brooding behavior, and eggs must be artificially incubated.³²

GENDER DETERMINATION

Many gallinaceous birds show a marked sexual dimorphism. The size (height and width), the body mass (weight), the color of the plumage, the shape of certain feathers, the presence of spurs, and the length and color of the tail feathers assist in gender determination between adults of some species (Table 38.6). In some breeds of domestic fowl, fertile cocks may have plumage that resembles that of hens.

Highly skilled individuals can determine gender by examining the cloaca in 1-day-old chicks or adults. The cloacal examination in newly hatched chicks of small bird species must be carefully done. Holding a chick too tightly can cause asphyxiation. Restraint of a chick for gender determination should start by gently pressing on the abdomen from both sides distal to the keel bone to

^{*}Some species of the genus are very similar, but not identical

stimulate defecation. The procedure is then similar to that described for Anseriformes (see Chapter 36, Management of Waterfowl).

Behavioral clues like dominance and certain mating rituals may suggest a gender but are not always indicative. Under certain conditions, the hens of some gallinaceous birds behave like and can have plumage like the males. DNA analysis or endoscopic examination of the gonads provides definitive determination of gender in species with similar morphologic characteristics.

ARTIFICIAL INSEMINATION

Artificial insemination is of economic importance in the domestic turkey and domestic guinea fowl. Domestic turkey cocks, like domestic fowl cocks, are fertile year-round, except during periods of extreme heat or during the molt period. Domestic guinea fowl cocks are not fertile all year and artificial insemination is used to induce year-round production.

The semen is collected by massaging the caudal region of the back or the abdomen, followed by stimulation of the cloaca. Fecal contamination of the semen may occur. It is best to collect the semen directly from the spermatic duct with a syringe and a blunted hypodermic needle. The semen may be diluted with Ringer's or Tyrode's solution by up to a factor of three.

Avian semen has a short half-life and must be used as quickly as possible. The semen is introduced with a syringe and a blunted hypodermic needle into the hen's oviduct. It is best to inseminate the hen just after she has laid an egg. This ensures that the oviduct is open, providing the semen with unrestricted access to the infundibulum.

Restraint

Cocks with spurs can injure handlers, especially when they become increasingly aggressive during the mating season. The beak also can serve as a weapon. Although serious injuries are rare, the face and the eyes of handlers should always be protected from a bird's beak, even in small species. The legs of a gallinaceous bird should be the initial focus for restraint.

Catching gallinaceous birds in an aviary can be done gently with a long, hooked stick. The birds should never be restrained by the feathers alone. The whole body must be secured to prevent a shock molt. Shock molt is most common in tail feathers but other feathers can be involved. Birds can be nearly "bald" after several failed restraint attempts. In larger species, the base of the wing is fixed along side the body with one hand and the legs are controlled with the other hand. The abdomen should be supported from below. If assistance is not available, a large bird can be restrained against one's body. Birds can usually be calmed by placing a loose-fitting, lightweight cotton sock over the head to reduce vision.

Disease Considerations

Gallinaceous birds are susceptible to a wide variety of viral, bacterial, mycoplasmal, parasitic, chlamydial, rick-

ettsial and fungal agents (Table 38.7). Information on these diseases may be found in other literature.

NUTRITIONAL DISEASES

Vitamin C deficiency does not occur in most birds; however, it has been reported in willow ptarmigan chicks and may occur in other grouse chicks. Though the chicks are able to produce endogenous vitamin C (as all gallinaceous birds probably can), the internal production is not sufficient in the first weeks of life, and has to be augmented by the intake of vitamin C from natural food plants (eg, blueberries). Clinical signs of vitamin C deficiency are abnormal behavior, enteritis, ruffled plumage, weakness of the wings and legs, bone fractures, retarded growth and death before the age of 4 weeks. Characteristic necropsy findings include weight loss, pale and edematous skeletal muscles, petechial hemorrhage in the muscles and mild subcutaneous edema. Fractures in the diaphysis of the humerus, radius, ulna, femur and tibiotarsus with massive callus formation and lateral twisting of the tibia also may occur. Feeding chicks natural foodstuffs high in vitamin C will prevent deficiency. Birds with poor quality diets often develop pododermatitis (Fig 38.6).

INTEGUMENT CONCERNS

Amputation of the comb or the wattles may be indicated following extensive injury, infection or frostbite. Adequate hemostasis is necessary to prevent fatal hemorrhage. Occasional trimming of the keratinous tip of the bill is necessary if the horny layer grows too fast, or if insufficient abrasive materials are available to facilitate

Fig 38.6 | Chickens on poor-quality diets often develop bumblefoot. The pain from the bumblefoot causes chickens to lay down frequently, which may lead to sternal ulcers.

Mediorhynchus papillosus

 External parasites like lice, fleas, flies, mosquitoes, midges and ticks occur in most gallinaceous birds. Mites occur above all in intensively reared gallinaceous birds, predacious bugs in some gallinaceous birds. normal wear. The excessive horn is pared off prudently with a sharp knife without cutting into the viable parts of the bill.

Cannibalism may occur in some Galliformes and is characterized by vent picking, feather pulling, toe picking, head picking and egg eating. Overcrowding, incorrect feeding, an inappropriate daylight cycle, high light intensity, poor housing conditions (eg, high proportion of toxic gases in the air), genetic predisposition and other factors may all promote cannibalism.

Beak trimming has been successful in commercial poultry production facilities, when performed by experienced personnel, to reduce the incidence of cannibalism and resulting injury. Removal of the comb and wattles is sometimes performed by commercial poultry breeders to reduce losses associated with aggressive behavior, especially associated with males. These procedures may not be suggested in gallinaceous birds raised for hobby. When performed improperly, these procedures may interfere with the bird's ability to eat, may result in infection and even affect the bird's social ranking in the flock. The bill is not only important for the uptake of food but also has sensory functions and is necessary for preening. Damage to the beak should be considered a substantial handicap. In most cases, cannibalism can successfully be prevented by correcting the deficiencies in the birds' environment; however, once feather picking is started, beak trimming or other management changes such as separating the birds or use of an anti-picking ointment^a may be necessary to break the cycle (Fig 38.7).

Trimming of the flight feathers in one wing can be used to prevent birds from escaping from open aviaries or to reduce the mobility of an aggressive cock during the breeding period. Usually all but the outermost two primaries and the innermost three secondaries are transected, creating an effective and cosmetic wing trim. With one wing trimmed, the bird is unbalanced and cannot gain speed during flight. Because the feathers will be replaced during the next molt, trimming must be repeated annually in adults. Under certain circumstances, it may be necessary to trim both wings. Other methods like pinioning or cutting the short tendon of the *extensor* carpi radialis make birds permanently unable to fly. The client should be made aware of the consequences of these procedures. Birds unable to fly or ambulate normally would be more susceptible to attack by pets and wild animals such as raccoons. In many countries, such practices are outlawed for humane reasons.

VACCINATION CONSIDERATIONS

Vaccination programs used in the commercial broiler, turkey and layer industries may be very comprehensive

Fig 38.7 | Anti-picking lotion may help reduce cannibalism.

and complex. These enterprises often have large numbers of birds, 1 million or more in many cases, on a single premises. Thus, disease prevention rather than treatment is the goal. Disease prevention is achieved through strict programs whereby disease organisms are prevented entry onto the premises by using biosecurity and by vaccination. Vaccination programs for each farm unit are designed specifically to provide maximum protection to the birds, while being economic and causing minimum stress to the flocks. Disease challenge risk in an area also must be considered in the program design.

In collections where gallinaceous birds are maintained, the goal likewise should be disease prevention by preventing entry of disease organisms onto the premises. Vaccination, as the second line of defense, is important in reducing losses in high-risk areas where disease challenge occurs. The primary obstacle in vaccinating collections of gallinaceous birds is availability of quality commercial vaccines. Vaccines for fowl are readily available for commercial use, but not for smaller collections. Due to market considerations, poultry vaccines are produced in vials containing 3000 or more doses per vial. Once vaccines are reconstituted, in the case of lyophilized products such as pox, infectious bronchitis, Newcastle, infectious bursal disease and infectious laryngotracheitis, they must be administered promptly (within 2 hours). As only small numbers of birds may be vaccinated at a time, vaccination may not be feasible. Other vaccines such as Marek's require storage in liquid nitrogen and must be administered to chicks promptly after hatching to be effective. These vaccines also must be used within 1 hour after careful thawing and mixing of the vaccine, as they are very fragile, cell-associated products. In the case of Marek's disease, birds will be exposed to this ubiquitous field virus soon after hatch in most instances, thus prompt vaccination is essential if it is to be efficacious (Fig 38.8).

Vaccination programs for gallinaceous birds in smaller collections are therefore limited to diseases that are more

Fig 38.8 | Vaccination of recently hatched chicks against Marek's disease.

virulent in nature and are high risk in a particular region. A disease such as infectious bronchitis, which causes only a mild and transitory respiratory condition in some gallinaceous birds and in which multiple serotypes are circulating, often is not considered for vaccination.

Diseases commonly considered for vaccination if endemic or if virulent strains are of concern in the area include Marek's disease, infectious laryngotracheitis, pox, Newcastle and infectious bursal disease (Figs 38.9a,b).

Although live-type vaccines are labile and must be stored under refrigerated conditions in the dark, have expiration dates, are sold in doses of 5000 or more per vial, and the contents of the vaccine must be used promptly following reconstitution, vaccination would often be indicated for valuable collections. Veterinarians, often working with clients from a number of collections, may divide the lyophilized vaccine pellet prior to reconstitution, using aseptic technique, to reduce vaccine waste and cost.

Vaccinations are often used in response to post mortem diagnosis. This is not always possible (Fig 38.10).

Management of

Canaries, Finches and Mynahs

PETER SANDMEIER, Dr med vet, Dipl ECAMS; PETER COUTTEEL, DVM

Fig 39.1 | A white recessive color canary is shown.

Fig 39.2 | A red color canary is shown.

The order Passeriformes (Table 39.1) is the largest of all avian orders and consists of 63 families comprising 5206 different species. The order is extremely heterogeneous, containing granivorous, insectivorous, frugivorous, omnivorous and carnivorous species ranging in size from a few grams to over 1 kilogram.

The species commonly seen in private veterinary practice include canaries, New World finches, Old World finches, waxbills, cardinals and mynahs (see Table 39.1).

The canary (*Serinus canarius*) can be considered a domesticated species. Spanish monks in monasteries as far back as 1402 achieved first breeding. Following a French expedition to the Canary Islands, this bird was introduced to France and Italy and later into the rest of Europe.¹⁷ Nowadays, canary fanciers have a wide range of activities, including preservation of old and rare breeds as well as breeding new color mutations.³² An important aspect of their hobby is showing and judging their birds. There are three groups of canaries: song canaries, color canaries and form canaries.

Song canaries include Harzer (Germany), Malinois (Belgium), Timbrado (Spain) or American singers (USA). Color canaries are divided into two groups. The melanin group includes black, brown, agate and isabel birds. The lipochrome group includes white (Fig 39.1), red (Fig 39.2) and yellow (Fig 39.3) canaries.

Form canaries are a diverse group, distributed among "frill," "type," "shape," "crested" (and "crest-bred") and "feather pattern" birds. Frills include Parisian frill, Frisé du nord, Frisé du sud, Frisé Suisse, Gibber Italicus, Giboso Espagnol, Padovano and Fiorino (Fig 39.4). Type

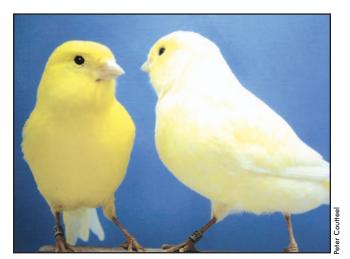

Fig 39.3 | A yellow color canary is shown.

canaries include Belgian bult, Scotch fancy, Münchener, Japan hoso, Lancashire, Yorkshire, Berner and Rheinländer. Shape canaries include border, Fife fancy, Norwich, Raza Espagnol and Irish fancy. Crested and crest-bred birds include Gloster consort, Gloster corona and German crest. The Lady Gouldian Finch is a popular finch amongst fanciers (Fig 39.5).

Anatomy and Physiology

Some anatomic and physiologic characteristics observed in canaries and finches include an extremely high basal metabolic rate and high body temperature (42° C, 108° F). The foot of the passerine bird is anisodactylous: 3 digits forward and 1 digit backward. 105 All passerine species have a crop, but in canaries and finches, the crop is much smaller than in psittacines, pigeons or chickens. There is no production of crop milk, but crop contents are regurgitated to feed the young. A proventriculus and ventriculus are present; the cecae are rudimentary. The spleen is oblong rather than spherical. Nestling Estrildidae finches have species-specific luminous mouth patterns to attract their feeding parents.⁷¹ The right and left nasal sinuses do not communicate as they do in Psittaciformes. Song canaries and other species are able to produce two sounds simultaneously by using both bronchial ends of the syrinx. The neopulmo as well as the paleopulmo divisions of the lungs are well developed in Passeriformes. Most Passeriformes have seven air sacs as opposed to the nine air sacs in Psittaciformes. The cranial thoracic air sacs are fused to a single air sac, as are the clavicular air sacs.71

Fig 39.4 | A form canary, Parisian frill, is shown.

Fig 39.5 | Lady Gouldian finches are dimorphic with the male in front showing the most and brightest color. The female in the background has less color especially on the head.

Table 39.1 | Selected Passeriformes Families

Family	Scientific name	English name	German name
Corvidae		Crow, jay, magpie	Krähen
Sturnidae		Starling	Stare
	Gracula religiosa	Hill mynah	Вео
Passeridae		Sparrow	Sperlinge
Ploceidae		Weaver	Webervögel
Estrildidae		Waxbill	Prachtfinken
	Poephila guttata	Zebra finch	Zebrafink
	Chloebia gouldiae	Lady Gouldian finch	Gouldsamadine
	Erythrura spp.	Parrot finch	Papageienamadine
	Lonchura striata var. domestica	Society or Bengalese finch	Japanisches Mövchen
Fringillidae		Finch	
	Serinus canarius	Canary	Kanarienvogel

	Pyrrhula pyrrhula	Bullfinch	Gimpel
Emberizidae	Melopyrrha nigra	Cuban finch	Kubafink
	Cardinalis	American Cardinal	Kardinale

Reproduction¹⁹

BREEDING FACILITIES

Nowadays, canaries are mostly bred indoors, often within a building in the garden or close to the house (Fig 39.6), sometimes inside the house in a cellar or an attic. The birds are kept in pairs in breeding cages ($50 \times 40 \times 40 \text{ cm}$) and require artificial lighting. In a traditional European facility, each cage would have drinking water, seed mixture, soft food, cuttlefish bone, grit, nesting material, conditioning seeds and bath water that is changed on a regular basis. The most suitable substrates for the cage bottom are newspaper, plain brown paper or small pieces of wood. Some breeders use cages with wire bottoms. Wire is easy to clean but can be dangerous for the youngsters sitting on the bottom of the cage as entanglement of the feet may occur.

Some breeding facilities have cages with nest boxes inside the breeding cage; others have breeding cages with the nest boxes outside (Figs 39.7-39.9). In order to collect or candle the eggs and leg band the youngsters, it is easier to have outside hanging nest boxes. Additionally, breeders have found that leaving a clutch with the parents until weaning leads to fewer babies produced each year. If they try to let the parents breed with the babies present, the subsequent eggs may be infertile because the babies interfere with the breeding process in some way. The parents may be disturbed and not incubate the eggs properly or the parents may abuse and pluck the youngsters, trying to drive them away. To overcome this, the babies are maintained in accessible but separate enclosures. Where outside hanging "baby cages" are used, the youngsters are fed through the wire. The youngsters of the first clutch are put in a cage next to the parents, separated by a wall containing 2-cmdiameter openings (Fig 39.10). The parents can prepare for the next round of eggs and babies more successfully, while continuing to feed the first clutch through the holes until they are completely weaned.

After weaning, the youngsters are put together in large cages so they can exercise their flight (Fig 39.11). Individual perches are very important to prevent picking. Often an older male is placed together with the youngsters to feed those that still beg for food.

BREEDING PERIOD

In Europe most breeders artificially extend the daily photoperiod. The reasons for using this technique of light manipulation are: 1) to control the breeding period and start reproduction before the natural breeding season (so most intensive work is done before July summer holidays); 2) to prepare the youngsters for the exhibitions at

Fig 39.6 | A canary breeding facility with netting on the windows helps prevent mosquito problems.

Fig 39.7 | Breeding cage separates youngsters of the first clutch in a baby cage (left) from the breeding pair preparing the second round (right).

Fig 39.8 | Between every two breeding cages (with inside hanging nest pans), there is a common baby cage for the youngsters in a canary breeding facility.

Fig 39.9 | A nest box, outside the main cage, makes access easier.

Peter Coutteel

Fig 39.10 | Youngsters are fed by their parents on the other side through little holes in the separation wall of the cages.

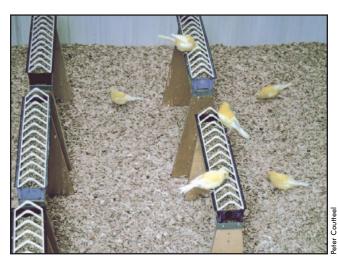

Fig 39.11 | Young canaries are housed in a large cage for flight exercise. Often an older male is placed together with the youngsters to feed them. The substrate is small pieces of wood.

the end of the year (molt period has to be completed prior to exhibition); and 3) to produce more clutches and youngsters. (Ed. Note: These techniques are used to improve profit and may not be ideal for the parent birds' over-all health).

TECHNICAL ASPECTS OF LIGHT

The spectrum of optical radiation lies between 102 nm in the ultraviolet (UV) and 106 nm in the infrared (IR) spectrums. This wavelength range is subdivided into seven bands: UV-C, UV-B, UV-A, visible light, IR-A, IR-B and IR-C. The UV-B band in natural sunlight allows for the multistep conversion of 7-dehydrocholesterol into 1,25 dihydrocholecalciferol (vitamin D₃), which is then reabsorbed by the skin or ingested during preening.98 Vitamin D₃ is very important for calcium metabolism. If there is a lack of incoming sunlight, full spectrum lamps can be used to induce the internal vitamin D production in the skin. Also, environmental contamination can be reduced by UV light. The action spectrum for inactivation of microorganisms reaches its maximum at about 265 nm (DNA absorption). If artificial light is provided for breeding birds, the kind of radiation produced by the lamps is an important factor.

Luminance

A minimum luminance (500 to 1000 lux) is needed (lux = lumen/m²). Lumen gives an indication of the total amount of light produced by a light source per second. Adding the lumen of all lamps present in the breeding room and dividing it by the square meters of the room will give an idea of the quantity of lux. Sunlight produces approximately 100,000 lux.

Frequency

Normal fluorescent lamps do not give continuous light, but flicker like a stroboscope at approximately 50 times per second (50 Hz). The human eye does not discern this frequency and the effect on the behavior of birds is not completely known. However, recent studies reveal that birds may have a spatial difference of 160 frames per second.⁶³

The stroboscopic effect of fluorescent light may lead to stress and may negatively influence the general condition of the bird. If many lamps are used at the same time or a combination of bulb lamps and fluorescent light is used, the stroboscopic effects will be less marked. The latest development is the HF (high frequency) lamp. These lamps have a frequency of 28,000 Hz, have a longer life and make dimming possible. When using artificial light, a dimmer should be used to simulate dawn and twilight. In Belgium, 92% of the breeders are using fluorescent lamps and 8% are using bulb lamps. 18

Color Temperature

Color temperature is the measure for descriptions of "warm" or "cold" light and is expressed in degrees Kelvin. Examples of color temperature include incandescent light (2700° K), warm white (3000° K), cool white (4000° K), daylight (5000° K), and cool daylight (6500° K). The higher the color temperature of the light (higher degrees Kelvin), the more blue the color of the light and the more UV light produced. Cool daylight b is ideal.

Ambient Light Temperature

Fluorescent lamps give the highest light output at a temperature of 20° C (68° F). These lamps are very sensitive to temperature. At a low ambient temperature, the buffer gases inside the lamp will disintegrate and there will be

less light output. Therefore, the use of multiple lamps simultaneously is recommended, in case of defects.

Nightlights

A small amount of light (7 W) during the night has a calming effect. If a bird is startled or otherwise disturbed, this lighting will allow it to regain its perch.

Photoperiodic Stimulation

The photoperiod is the ratio of light to dark. A 15:9 ratio means 15 hours of light and 9 hours of darkness. The photoperiod is very important in those species of birds that originate from zones with seasonal changes. In temperate-zone birds such as canaries, ovarian development and testicular growth are synchronized by a combination of increasing day length, the presence of a partner and an available nesting site.⁹³

The normal physiologic pathway for photoperiod stimulation has been described.⁹³ Retinal photoreceptors give stimulation through the optic nerve to the hypothalamus. Releasing hormones from the hypothalamus stimulates the adenohypophysis to produce gonadotropins, which, in turn, stimulate the gonads to release sex hormones. Another factor that can stimulate the hypothalamus is the presence of light rays that penetrate the spongy bones of the head.⁹³

These stimulating factors encourage testicular growth in the male bird (up to five times in size) and production of fertile sperm. In the female bird, strong development of the ovaries and follicular growth occur. Experience shows that male canaries need a slightly longer exposure to extended daylight than females. This can be obtained by placing the males in isolation 2 weeks in advance, so that light stimulation may begin earlier. The reason that males need a longer preparation period is probably due to the fact that, in nature, males receive extra incentives, such as the song of another male while marking out their territories and trying to attract a partner. These incentives are often not present in an artificial breeding situation.

The Role of Daylight Length

Most problems in canary breeding are due to errors in the manipulation of the light cycle. Canaries need a minimum of 14 to 15 hours of daylight to begin breeding (nest building and production of eggs). With this amount of light, they are also able to feed their youngsters adequately and raise them properly. The cycle of light is also a major factor in determining whether breeding is sustained. If the length of daylight is submitted to fluctuations, the birds may receive conflicting hormonal incentives and negative endocrine feedback. The result can be an early molt and the birds may cease breeding. There

are two methods of manipulating the length of daylight.¹⁸

Gradually Increasing Daylight Length:

Using this technique, the amount of daylight is gradually increased on a weekly basis. Depending on how quickly this is done, it may take a period of 2 months to extend the 8 to 10 hours of natural daylight to 15 hours. If a weekly addition of 30 minutes (5 additional minutes per day) is used, it will take approximately 10 weeks to obtain this result. This means that the fancier needs 2 to 3 months preparation before breeding can begin. Gradually increasing the length of the day is closest to natural stimuli and is used by more than 80% of the fanciers. Fifteen hours of daylight length appears to be ideal. Poor annual breeding results with higher chick mortality occur when the daylight length exceeds 17 hours.

Immediate Increase to Full Daylight Length:

The daylight length can also be increased suddenly from 10 to 15 hours. In this case, the birds reach breeding condition after 3 to 4 weeks, but most are unable to maintain good results throughout the full breeding season. However, some fanciers do have good results with this method. This method of sudden increase, used by approximately 10% of the breeders, often leads to poor fertilization of the first clutch, which normalizes subsequently, and higher mortality of females.

BREEDING CONDITIONS

Normally, canaries will begin breeding when the following conditions are fulfilled: photoperiod stimulation and appropriate minimum daylight length (as discussed), maturity, good health, an acceptable partner, presence of nest and nesting material and a minimum temperature of 15° C (59° F), during daytime.

Maturity

Most canaries will reach sexual maturity in a few months but good fertility will only start at approximately 10 months of age. Sometimes there are fertility problems when birds born in the last clutch of the former year are bred too early in the following year.

General Health

Many diseases and breeding failures in captive Passeriformes are the result of husbandry problems. Medication is often incorrectly used to attempt correction of husbandry-based problems. Primary infectious disease is less commonly encountered. The ideal avian veterinarian/aviculturist relationship starts before the breeding season when the birds are routinely examined. A physical examination is performed to determine whether each bird is in good condition. Examination includes the head (eyes, ears and nares), abdomen (liver, gastrointestinal tract),

Fig 39.12 | A nesting material ("sharpie") of small white fibers of cotton is well accepted by canaries.

Fig 39.13 | Small white fibers of cactus (Agave *rigidus*) are another source used for nesting material.

feathers (state of molt, external parasites and discolorations), wings (lacerations, feather cysts), feet and digits (hyperkeratosis, pox lesions and pododermatitis). Crop swabs are collected to determine if trichomoniasis or candidiasis is present. Fecal samples are taken for bacteriology, and blood samples are collected by venipuncture for serologic diagnosis of paramyxovirus and avian influenza. Finally, a fecal examination is performed to assess for coccidiosis, macrorhabdosis, helminth infections, yeast, protozoal cysts (*Giardia* sp.) and cochlosomiasis (diagnosis of cochlosomiasis requires fresh, warm stool). Sometimes a fecal Gram's stain is performed to interpret the levels of gram-positive and gram-negative bacteria and for the detection of *Candida* and *Macrorhabdus* spp.

Acceptable Partner

In canary breeding, there are generally few problems with the acceptance of the partner. Even during the breeding season, the female bird allows copulation with a different male for each round. If necessary, male birds can be used for several females simultaneously, with a maximum of three females for each male.

Nest and Nesting Material

Breeders use several different types of nest pans. Plastic nest pans have a very smooth surface that is easy to clean and makes movement of the nest possible. Often, holes are drilled in the bottom of the nest in order to attach the nest with wire. Stone nest pans can be well impregnated with a water-soluble insecticide. Sometimes self-made wooden or bamboo nest pans are used. They have the disadvantages of being difficult to clean and disinfect and must be changed after every clutch. Several types of nesting material are available. "Sharpie" consists of small white fibers of cotton, washed and cut in small pieces of approximately 3 to 4 cm (Fig 39.12). This nest-

ing material is well accepted by canaries, and most Belgian breeders utilize it. Sisal fiber, of the plant *Agave rigidus*, is a very fine organic nesting material (Fig 39.13). It is important to note that constriction of a digit can occur due to entanglement in the fine fibers. If not treated, vascular necrosis and digit loss can result. Horsehair and moss are no longer used because they cannot be disinfected.

Temperature and Humidity

Most fanciers maintain the temperature in the breeding room at approximately 15° C (59° F) at the start of the breeding season. If the temperature is higher, the females start laying eggs even before pairing. Temperature is regulated with various heating devices (electrical, central heating, gas and fuel oil). During the breeding season and summer, the temperature may fluctuate. Therefore, good ventilation should be provided to remove exhaust gas and to eliminate temperature extremes. The temperatures should range from 15° to 25° C (59-77° F). In the authors' experience the temperature should not exceed 35° C (95° F).

The humidity in the breeding room should be kept within the range of 60 to 80%. Maintaining the humidity at the lower end of this range minimizes the development of pathogens. It is important to have sufficient humidity at the time of hatching. Therefore, breeders often moisturize the eggs just prior to hatching with a spray of warm tap water in the nest or by plunging the eggs for a second into a cup of warm water $(40^{\circ} \text{ C}, 104^{\circ} \text{ F})$.

PREPARATION FOR THE BREEDING PERIOD

Trimming

Before pairing birds, each bird should be physically

Fig 39.14 | The pericloacal region of a canary (Gloster corona) is trimmed 1 cm ventral to the cloaca to prevent the feathers from interfering in semen transfer.

examined and eventually "trimmed". Because of the heavy plumage of some canary varieties (especially type canaries), it is preferable to trim the plumage surrounding the pericloacal region approximately 1 cm above the cloaca and horizontally prior to breeding (Fig 39.14). This reduces the potential for the caking of excrement around the vent and may increase the possibility of copulation. The nails should be checked and cut shorter if necessary so that good positioning is possible during copulation. Loose perches should be repaired prior to nail trimming. Trimming of the eye feathers can also be important so that the male can see the female. Sometimes there is an overgrowth of the upper beak, which can be trimmed with an electric grinding tool.^a Traditionally, breeders used cuttlebone for that purpose, but recent nutritional experience shows the problem is more complex than just calcium deficiency and a lack of beak exercise. Nutritional assessment is important in birds with overgrown beaks.

Disinfecting

The breeding cages should be disinfected before introducing birds. No single disinfectant is active against all microorganisms or useful in all situations, so the chemical must be carefully chosen. Commonly used and readily available disinfectants include sodium hypochlorite (household bleach), quaternary ammonium products, chlorhexidine, glutaraldehyde and formalin.

Cleaning and disinfecting the breeding cages, perches and nest pans should be performed prior to introducing the birds. Also, prevention of red mites, northern mites and lice with an appropriate insecticide is advised. A common product utilized in Belgium is permethrin. Alternative pest control agents include insecticidal soaps used for plants, fresh garlic and diatomaceous earth. When using diatomaceous earth, the unpolished form

(used for swimming pool filters) should be selected. When this form of diatomaceous earth is dusted onto the birds, the needle-like points penetrate the insect's exoskeleton causing desiccation. To reduce mosquitoes, mosquito netting or screened windows may be necessary. The carbon dioxide generator has advanced outdoor control. Female mosquitoes feed on blood, to which they are attracted by exhaled carbon dioxide. A new machine uses bottled gas to generate the CO₂ bait. The mosquitoes are then trapped in an inescapable collection bottle. If used as directed and combined with traditional preventive measures, mosquito population control is achieved.

Some canaries are housed outside in open aviaries, in which case, disease control and medicating individuals can be impractical. It is difficult to completely eliminate infectious agents once they are introduced into a planted aviary. Free-living birds and rodents may be transmitters of protozoal diseases, helminth infestations and bacterial infections.

PAIRING BIRDS

It is important to predetermine the sex of the individual birds in order to ensure they are paired appropriately. In males, the caudal end of the ductus deferens forms a mass called the seminal glomerulus. During the breeding season, the seminal glomerula push the cloaca walls into a "cloacal promontory" (Fig 39.15). Females do not develop this projection and have a flatter vent (Fig 39.16). The male is placed into the female's cage when the birds are ready for pairing. In the classic situation, one male and one female are together for the whole breeding season and rear the youngsters together. Alternatively, one high-quality cock may be used for pairing with several females. After copulation, the male is separated, and each female will rear her youngsters alone. Fertile sperm may be stored in the female's sperm glands (tubular glands within the oviductal wall located at the uterovaginal junction) and may fertilize eggs for approximately 8 to 10 days.93

The regulation of sexual behavior is altered by the effects of social interactions (eg, song of other male birds), which can exert powerful effects on reproductive success and overall well-being of the individual birds.⁸⁰

Genetic Considerations

There should also be appropriate genetic selection of breeding birds regarding origin, color, type and feathers. Feather cysts are usually seen in the Frill, Norwich and other soft feather breeds and are believed to be a genetic disorder. Likewise, cataracts in canaries may have a genetic origin.³⁵

Fig 39.15 | A male canary is trimmed in the pericloacal region. The cloaca is perpendicular to the tail and points down, a "cloacal promontory".

Fig 39.16 | A female canary is also trimmed in the pericloacal region, but the cloaca points in the same direction as the tail.

Other genetic abnormalities may cause mortality. One example of this is seen when pairing crested canaries such as the gloster (with crest = corona, without crest = consort).71 The corona gloster is heterozygous for the autosomal crest gene. Birds that are homozygous for the crest gene die. Pairing a corona with a consort yields 50% corona and 50% consort. Pairing two corona phenotypes will yield 25% consort, 50% corona and 25% dead chicks. Another example of genetic mortality occurs with the dominant white color gene. Canaries that are homozygous for the white gene die,71 while heterozygous birds are white. There is 100% mortality in chicks if two heterozygous dominant white birds are paired. If white birds are paired with other colors, 50% of the chicks will be heterozygous for the dominant white gene and 50% will be the other color.

EGG COLLECTION

During the egg-laying period, eggs are collected and replaced with artificial eggs while the female continues to lay her clutch. The eggs are kept in a cool place (15 to 20° C, 59 to 68° F, humidity 60 to 80%), in numbered boxes with seed at the bottom and put back into the nest when the female starts sitting. This is done to achieve uniform growth in the youngsters. The average clutch size of type canaries is 4 eggs. Color canaries often have a clutch size of 4 to 7 eggs. One should avoid writing on the eggs, especially with an alcohol pencil. Also, soft cloth or rubber gloves should be used while handling eggs in order to avoid contamination (eg, hand creams and cosmetics), which can result in the death of the chick.

Nutrition

Most passerines are primarily seed-eating birds. They may consume up to 30% of their body weight in food daily (compared with 10% for larger parrots). The basal metabolic rate is approximately 65% higher than in non-passerines. Granivorous birds are believed to need grit for digestion.³²

The majority of commercially available seed mixtures are multideficient.³² Seeds are deficient in vitamins A, D₃, E, K, lysine and methionine and have a poor Ca/P ratio. In Belgium, seed mixtures for canaries contain canary seed (62%), Niger seed (2%), rapeseed (22%), hemp seed (3%), peeled oats (8%) and linseed (3%). During the winter, 50% canary seed is mixed with this seed mixture to prevent obesity. Research has shown the white canary has a much higher vitamin A requirement level than other canaries.³⁷

For good health and breeding results, canaries are traditionally fed soft food (egg food). The formulas of available commercial egg foods vary greatly. The current recommendation is to follow the advice of an experienced passerine veterinarian, as several formulas are used with good breeding results. They contain essential vitamins, amino acids and minerals. During the breeding period, soft food should be given on a daily basis and offered fresh three times a day. Most of the available soft food contains 16 to 18% protein. Soft food is often moisturized just before administration to make it more acceptable. Sometimes soaked seed or couscous is mixed with the soft food to improve the taste. Soaked, germinated seeds contain many additional vitamins.

Soluble grit sources, such as cuttlefish bone (Sepia spp.),

oyster shell, limestone (calcium carbonate), marble (crystalline limestone) and gypsum (calcium sulfate), are used as calcium supplements and are usually completely digested by birds. Insoluble grit consists of items such as sand, quartz and granite and can lead to health problems (eg, impaction of the crop, proventriculus and gizzard) if it is overconsumed.¹⁰⁹ Beach sand is shell (and soluble), but contamination with salt excludes its use.

Fruits, vegetables and many free-growing plants such as dandelion, chickweed and parsley are good sources of fiber, vitamins and minerals.

Sometimes color additives are used to manipulate the color of the plumage. For example, red-colored canaries are fed canthaxantines or \(\mathbb{R}\)-carotene 2 weeks before the breeding season until the end of the molt period. Spirulina algae is known as a natural source of coloration, however, it may not be effective to acquire the level of coloration desired. Yellow-colored canaries are supplemented with lutein for enhancing the desired "yellow color" for exhibition.

Because of the poor rate of breeder performance and a high rate of nutritional disorders on the seed-supplemented diet, trials offering pellets or mash containing a balanced proportion of the required nutrients are proving a good alternative to a traditional diet mentioned previously. One should not indiscriminately supplement a formulated diet with calcium, vitamins or minerals.

Most small passerines drink from 250 to 300 ml/kg body weight of water each day (desert birds such as zebra finches are an exception).⁷¹

Diagnostic Procedures

HISTORY AND PHYSICAL EXAMINATION

A careful consideration of the history is essential because the physical examination and other diagnostic procedures are often not rewarding in Passeriformes due to the size and nature of the birds (Table 39.2).

Examination of Cage or Aviary

Pet birds will often be presented individually or in a small group in their own cage. Points to observe include size, hygiene status, perches, substrate, food and water containers, toys and cuttlefish bone or other supplements. Although this might not give much information about a certain disease, it will help assess the owners and their standard of knowledge regarding hygiene, nutrition and general requirements of the birds.

Table 39.2 | Checklist of Questions to Obtain Patient History

- Number of birds owned, number of sick birds
- Clinical Signs
- Age of affected birds
- Species, breeds involved
- · Diet: seed mixture, soft food or formulated diet
- Food supplements (eggs, soaked seeds, vitamins, trace elements, amino acids, live food)
- Drinking water supplements (vitamins, trace elements, amino acids; frequency)
- Breeding method (artificial light, foster parents, baby cages)
- Vaccinations (poxvirus)
- Contact with birds (newly acquired, shows)
- Medications already given

When dealing with a breeding facility, the aviary should be visited. This is the only way to assess important aspects such as general hygiene, nutrition and management procedures.

Observation of the Bird

Before handling and restraining a sick bird for a physical exam, it should be observed from a distance, either in its own cage or, if it is presented in a cardboard box, in a small cage that can be placed directly on a scale.

Restraint and Physical Examination

A systematic approach with good restraint of the bird is important. This allows the physical exam to become routine, which shortens the procedure and reduces the stress factor to the often already compromised patient. The systematic approach assures that nothing is overlooked.

The necessary equipment and basic procedure for performing a physical examination are listed in Table 39.3.

DIAGNOSTIC SAMPLING

Fecal Examination

A direct wet mount of fresh, warm stool should be examined for *Cochlosoma*, *Giardia*, *Candida*, *Macrorhabdus*, bacteria, plant material, chitin skeletons, urates and powderdown feathers. Gram's stains should not contain *Macrorhabdus*, yeast (*Candida*) or bacteria (or only low numbers of gram-positive rods or cocci). Flotation can reveal coccidian oocysts (common), or helminth eggs (seldom seen in canaries and finches).

Crop Swabs

A crop swab can be obtained by using a cotton-tipped applicator moistened in saline (Fig 39.17) or by administration of approximately 0.2 ml saline into the crop with a syringe and small feeding needle and then re-aspirating

Fig 39.17 | A cotton-tipped applicator in saline is used for a crop swab.

Fig 39.18 | The right jugular vein in a canary is used for blood sampling.

Table 39.3 | Physical Examination Checklist

Equipment

- Paper towel for capture and restraint
- Jeweler's loupe (for magnification)
- Bright light source (otoscope or endoscope light source)
- Alcohol
- Aural thermometer
- · Digital gram scale
- Small observation cage

Procedure

- · Prepare all necessary equipment.
- Capture and restrain bird with a paper towel.
- Listen for respiratory sounds.
- Extreme respiratory distress warrants releasing the bird and considering delay of further procedures. Exceeding the oxygen reserve of a small passerine with respiratory impairment can be rapidly fatal.
- Examine the eyes, ears and nares.
 Look for exudates, crusts, pox lesions,

- cataracts, sinusitis.
- Examine the oral mucosa and tongue.
 Look for white plaques (candidiasis, bacterial infections, trichomoniasis).
- Measure body temperature using aural thermometer, which is a fast, low-stress method. Use three readings for an average temperature. In sick small passerines the body temperature is below 40° C (104° F).
- Assess the pectoral muscle mass and color (anemia) and the presence of fat.
 Look at the skin for signs of dehydration (red, dry skin).
- Examine the abdomen. Assess the internal organs, which can be observed easily through the abdominal wall for signs of hepatomegaly, dilatation of the intestines, ascites or presence of urine in the cloaca. (If the feathers cannot be parted correctly consider applying a drop of alcohol over the

- abdomen. Be aware that this can cause hypothermia).
- If necessary wet feathers over neck and observe trachea for mites.
- Examine the feathers for the state of molt, ectoparasites, broken feathers, discoloration, alopecia or dirty feathers around the vent and along abdomen.
- Examine the wings and legs for skeletal deformities, fractures, wounds and feather cysts.
- Examine the feet and toes for signs of hyperkeratosis, pox lesions and pododermatitis.
- Place bird in a small cage standing on a digital scale. Register weight. If necessary, cover with a towel.
- Only at this stage (after the bird is no longer in the hand), discuss findings and further testing with the owner.

it. A direct warm wet mount can reveal the presence of *Trichomonas, Candida, Macrorhabdus* or bacteria.

Samples for Bacteriology

Samples for bacteriology may include feces, a cloacal swab, nasal discharge or a skin swab.

Blood Samples

A blood sample may be obtained by venipuncture of the jugular vein (Fig 39.18). No more than 1% of a bird's body weight should be collected, unless this is a termi-

nal procedure for serology prior to euthanasia and necropsy. Hematology includes hematocrit, total protein and blood smear for blood parasites. Serology may indicate paramyxoviruses (PMV), *Chlamydophila* spp. or *Toxoplasma* spp. Table 39.4 lists selected normal hematologic and serum biochemical values.³⁵

NECROPSY

Necropsy is a good procedure to find the cause of death or to confirm a diagnosis, especially when dealing with flock problems. The carcass must be refrigerated imme-

Table 39.4 | Hematologic and Chemistries Reference Ranges

Parameter	Canary	Finch	Mynah

Table 39.5 | Necropsy Procedure

History:

- Number of birds owned, number of sick birds.
- Identification of carcass: species, leg band.
- · Inspect packing and feathers for ectoparasites.
- External examination: feathers, eyes, ears, nostrils, vent; condition of pectoral muscles.
- Wet carcass with alcohol and pluck feathers. Open carcass from sternum to cloaca as well as from sternum up to thoracic inlet and on along neck up to the mandible.
- · Assess air sacs and serosal surfaces.
- Remove heart, then the liver and intestinal tract, by cutting through the esophagus and bending the viscera away from the body cavity at the cloaca, leaving lungs, kidneys and gonads in the body.
- · Assess all organs macroscopically.
- Swab obvious lesions as well as liver and heart blood for bacteriological cultures.
- Slice all parenchymatous organs (liver, spleen, kidney, pancreas, lung, heart, gonads).
- Open all tubular organs (gastrointestinal tract, trachea).
- Direct wet preparation and flotation of gastrointestinal content.
- Cytology of impression smears of freshly cut surface of liver, spleen, lung, etc, and scrapings of the mucosa of crop, proventriculus and intestine.
- Collect tissues for histopathology in buffered formalin.
- Freeze tissue for virology.

diately after death, and necropsy must be performed within 72 hours. A systematic approach is essential (Table 39.5).

Treatment Techniques

DRUG ADMINISTRATION

Parenteral Administration

As in all avian species, drugs can be administered by intravenous, intramuscular or subcutaneous injection. Drug dosing should be based on the exact weight determined by an electronic gram scale and administered using a precise 0.3-ml insulin syringe, which permits dosing as little as 0.005 ml. Due to the size and nervous character of small passerines, most injectable drugs are administered by intramuscular injection into the cranial third of the pectoral muscle. Applying pressure on the injection site with a dry cotton-tipped applicator can control bleeding. In dehydrated patients, fluids can be administered subcutaneously in the inguinal skin fold.

Oral Administration

Direct oral administration allows accurate and regular dosing but is feasible only in individually diseased birds housed in a small hospital-sized cage. Expecting an owner to individually treat a flock of small passerines housed in a larger cage or aviary will result only in poor owner compliance and a counterproductive stressful situation for the birds being chased through the aviary twice a day.

Medication of the drinking water and soft food is often the only feasible option for flock treatment. Drawbacks of which to be aware include: 1) reduced and irregular water intake, resulting in inadequate or irregular blood levels with therapeutic failure and development of drug resistance; 2) no measurable blood levels during the night due to the high metabolic rate and rapid drug elimination; and 3) the potential for drug toxicoses in dry, hot weather (eg, dimetridazole or furazolidones). Oral drug administration should be via drinking water and soft food simultaneously. Dosages are listed in Table 39.6.34

ANESTHESIA

The anesthetic of choice is isoflurane (or sevoflurane) gas, as for other avian species. The bird may be captured and restrained using a paper towel and masked down with 4 to 5% isoflurane. Anesthesia can be maintained at approximately 1.5 to 2.0% isoflurane; the anesthetic depth can be adjusted by monitoring the respiration rate and reflex status. A suitable mask may include a syringe case, syringe or a dropper bottle with the base cut off.

Table 39.6 | Therapeutics Administered via Soft Food and Water in Flock Treatment of Canaries and Small Passerines

Drug	Concentration in Drinking Water (mg/L)	Concentration in Soft Food (mg/kg)
Amoxicillin	200-400	300-500
Amphotericin B	100-200	100-200
Ampicillin	1000-2000	2000-3000
Chlortetracycline	1000-1500	1500
Dimetridazole	125	_
Doxycycline	250	1000
Enrofloxacin	200	200

Toltrazuril	180	
Trimethoprim/sulfonamide	200	200
Tylosin	250-400	400

Note: The birds should be treated at the same time through the drinking water and through the food.

Data reprinted with permission from Dorrestein and Elsevier Science.32

Use of a heating pad as well as humidified anesthesia gas will minimize drying out of the mucous membranes and loss of body heat.

SURGERY

Surgery techniques are the same as in other avian species. Special considerations due to the small blood volume and the high metabolic rate include: the use of minimally invasive techniques (eg, removing egg-bound eggs from the cloaca and not by abdominal surgery), bipolar radiosurgical forceps (which allows for hemorrhage control), binocular magnification loupes and a good light source. Postoperative recovery should occur in a dark, warm incubator at 30° to 32° C (86-98° F).

FRACTURE SPLINTING

Fractures of the wing are relatively uncommon and may be treated by external splinting and bandaging with a minimal amount of padding. Fractures of the tarsometatarsus and tibiotarsus are more common. A sandwich adhesive or masking tape splint gives excellent results. The knee and tarsal joint are positioned in a moderately flexed position, and tape is applied to the medial and lateral sides of the fractured leg. The tape is molded to the contour of the leg using hemostat for-

ceps. Instant glue is applied to the outer surface of the tape and then a second layer of tape is applied over the glue-covered surface. The tape is trimmed to make it as small and light as possible. The patient is maintained under anesthesia for another few minutes to allow the glue to dry and form a hard, stable cast. This glue-hard-ened masking tape splint can be removed with scissors, with the patient under isoflurane anesthesia to avoid refracturing the leg.

Viral Diseases

POXVIRUS

Roughly 232 avian species in 23 orders have been reported to acquire a natural poxvirus infection. It is likely that many more species are susceptible to avipoxviruses. Many of these reported avian species belong to the order of Passeriformes. Poxvirus infections are particularly common in canaries (*Serinus canarius*) and other Fringillidae. Of clinical importance to the avian practitioner is canary pox. The disease is mainly transmitted from latently infected birds by bloodsucking insects, including mosquitoes and red mites.

Transmission can also occur through direct contact with an infected bird or indirect contact with contaminated objects such as gloves or hands. Because poxviruses are not capable of penetrating intact epithelium, they must enter the skin through abrasions (eg, caused by cannibalism, territorial behavior, feather picking, aggressive preening or handling and consumption of scabs). Theoretically, pox infections can occur during the whole year. However, most outbreaks are diagnosed in the late summer and autumn, because of the prevalence of mosquitoes. Birds of all ages can develop disease, but young birds (older than 3 weeks) are especially susceptible.

Clinical Disease

The three different clinically recognized symptoms are the cutaneous or external form, the internal diphtheroid form and the septicemic form.⁵⁹ Whereas finches often develop the cutaneous form, canaries will often develop the internal diphtheroid or septicemic form, making pox infections in canaries a disease with a high mortality.¹⁷

Cutaneous Form

This form is localized on the toes and legs and around the eyes, nares and beak (Figs 39.19a-c). These unfeathered body regions are easily accessible to blood-sucking insects. As the lesions progress they develop from papules of roughly 2 to 4 mm diameter to vesicles that open spontaneously, dry out and then become crusts. Tumor-like pox lesions that do not develop vesicles and

Figs 39.19 | a,b,c) Shown are pox lesions on the eyelids, back of head and sternum. d) A hemorrhage in the liver and enlarged spleen is shown in a bird with pox.

crusts have also been described.^{38,112} The contaminated birds rub their eyes and beaks against the perches. They also may pick the lesions on their legs until they start bleeding. The lesions can be treated locally with iodine, but often the bird will lose a nail or even a digit. The mortality rate, however, is low in this form and the lesions will heal spontaneously after 3 to 4 weeks.¹⁷

Diphtheroid Form

Lesions occur on the mucosa of the tongue, pharynx and larynx. The fibrinous lesions are gray to brown and caseous.⁵¹ In severe cases birds have difficulty swallowing or exhibit dyspnea.

Septicemic Form

This is the predominant form diagnosed in canaries. Birds show severe dyspnea and become apathetic and cyanotic. They are unable to eat or drink, and mortality can be as high as 90 to 100%. In contrast to other disorders, such as tracheal mites or bacterial infections of the upper respiratory system, the breathing is silent without clicking or growling sounds.

Diagnosis

Antemortem in-house cytology and postmortem histo-

pathology often reveal intracytoplasmic inclusions (Bollinger bodies) in epithelial cells.⁵⁹ Macroscopic postmortem findings are often unspectacular (Fig 39.19d).

Prophylaxis

Attenuated live vaccines^c that are applied using the wingweb method are commercially available for canaries and crossbreeds. A whitish swelling or scab at the injection site observed 8 to 10 days post-vaccination indicates a successful vaccination. Protection lasts approximately 6 months. Vaccination should be performed early in the year, prior to mosquito season. Solid immunity develops 2 to 4 weeks after vaccination. Fledglings should be at least 4 weeks old. Vaccination can be repeated without any risk if vaccination status is unknown. A new needle should be used for every bird so that blood-borne diseases, including poxvirus, are not transmitted. Vaccinated birds should be separate from newly acquired non-vaccinated birds.¹⁷

Treatment

There is no therapy for the septicemic poxvirus infection. Only a preventive vaccination offers solid protection. In case of an outbreak, the following measures should be taken: separate diseased birds (gasping birds and birds with cutaneous lesions), consider emergency vaccination and begin antimicrobial therapy against secondary bacterial and fungal infections. Multivitamin (especially vitamins A and C) supplementation may help with epithelial turnover and immune system support. Iodine should be applied locally to cutaneous and mucosal pox lesions. Non-steroidal antibiotic eye ointment may be applied. Access to blood-sucking insects must be prevented, and cages and perches much be thoroughly disinfected. An emergency vaccination in the face of an outbreak is controversial. This may result in the recombination between field and vaccine virus strains, inducing severe disease in the entire flock.⁵¹ Handling of the birds can also induce skin abrasions, creating a port of entry for the poxviruses.

Differential Diagnoses

The following should be considered as differentials for the cutaneous form of poxvirus infection: bacterial and mycotic dermatitis, *Knemidokoptes* mites, fiber constriction and conjunctivitis. *Trichomonas* and *Candida* should be considered as differentials for the diphtheroid form, and for the septicemic form, consider bacterial upper respiratory disease, *Atoxoplasma, Trichomonas, Sternostoma, Chlamydophila, Aspergillus, Syngamus* and *Paramyxovirus* (PMV) infections.

POLYOMAVIRUS

Avian polyomavirus (APV) has been associated with mortality in Passeriformes of all ages. Reports include disease in canaries, greenfinches (*Carduelis chloris*), goldfinches (*Carduelis carduelis*), Gouldian finches (*Erythrura gouldiae*), painted finches, golden-breasted starlings (*Cosmopsarus regius*), seedcrackers (*Pyrenestes* sp.) and bluebills (*Spermophaga haematina*). ^{22,48,71,99}

Recently, 20 different avian polyomavirus variants have been determined. 85 A parsimony tree was constructed containing three major branches. All European viruses were confined to Branch I, but APVs from the USA represented all three branches. Polyomaviruses from different avian species were also on each of the three branches, suggesting that species-specific pathotypes have not developed.

Clinical Disease

No specific clinical entity is recognized in birds with APV, but reported clinical signs include acute mortality, non-specific signs of disease (fluffed bird), delayed fledging, poor feather development, abdominal hemorrhages (Fig 39.20) and long, tubular, misshapen beaks in surviving fledglings.^{17,95}

Fig 39.20 | Abdominal hemorrhages in these Lady Gouldian finch (*Erythrura gouldiae*) chicks was due to polyomavirus.

Diagnosis

Serodiagnosis of APV has traditionally been performed using a serum neutralization test. Recently a blocked enzyme-linked immunosorbent assay for the detection of avian polyomavirus-specific antibodies was developed in Germany.⁶¹

DNA probes used to detect avian polyomavirus in psittacines are commercially available. This probe, however, will not detect the virus in seedcrackers. ⁴⁸ It does not appear clear in which passerine cases these probes are capable of detecting avian polyomavirus. A DNA in situ hybridization analysis using a probe designed to recognize nucleotide sequences coding for a major viral structural protein was highly sensitive in the detection of APV infection in seedcrackers and bluebills. ⁴⁸

Necropsy

Avian polyomavirus lesions that can be expected on gross postmortem examination include a pale swollen liver, splenomegaly, and perirenal, serosal, intestinal and hepatic hemorrhage.⁵¹ Histologic changes include inflammation and necrosis of the liver, spleen, myocardium, intestinal tract and bone marrow. These organs also will demonstrate intranuclear inclusion bodies.⁹⁵

Prophylaxis and Treatment

A commercially available inactivated avian polyomavirus vaccine for parrots has not been shown to induce protection in Passeriformes. In one case, over 80 Passeriformes of various species were vaccinated. The nestling mortality caused by polyomavirus did not decrease in the breeding season following the vaccination trial. 99 Other than supportive measures, there is no treatment for diseased Passeriformes. In aviaries experiencing high nestling mortality, discontinuing all breeding during one season can often control the outbreak of clinical disease.

Fig 39.21 | This melba finch (*Melba astrilde*) is exhibiting torticollis as a result of paramyxovirus (*PMV-3*).

Fig 39.22 | Papillomavirus with wart-like skin masses is shown in a siskin (*Carduelis spinus*).

Differential Diagnoses

Differential diagnoses include all pathogens causing sudden death in Passeriformes (Table 39.7).

PARAMYXOVIRUS

Of the nine known serotypes of paramyxoviruses (PMV-1 through PMV-9), only PMV-1, -2 and -3 are known to cause disease in Passeriformes. 96,104

PMV-1

As in all avian species, PMV-1 can cause a variety of disease signs in Passeriformes. These include watery diarrhea, respiratory signs, sudden death and, less commonly, neurologic signs.^{32,71} Most species of free ranging birds have been found to be susceptible to some strain on PMV-1. PMV-1 is a reportable disease in most countries.

PMV-2

PMV-2 infections in Passeriformes appear to be mild and self-limited. They are endemic in finches originating from northern Africa. Experimentally, they cause mild upper respiratory tract disease.⁵¹

PMV-3

The most common serotype observed in Passeriformes is PMV-3. Commonly affected species are African and Australian finches. 17,32 Clinical signs include conjunctivitis, anorexia, diarrhea, voluminous starchy stools, dyspnea and torticollis (Fig 39.21). 70,102,104 Diagnosis is based on serology or virus isolation. Serologically, there are cross-reactions with PMV-1. An exact differentiation is possible with monoclonal antibodies. 51 Virus isolation is performed by hemagglutination inhibition using antisera specific for PMV-3 on inoculated cell cultures. 59,104 Gross postmortem lesions can be minimal and are nonspecific. Histologic lesions consist of encephalitis, myocarditis and pancreatitis associated with intranuclear and intracy-

toplasmic inclusion bodies.¹⁰⁴ Although no commercial PMV-3 vaccination is available, an inactivated vaccine was shown to produce sufficient immunity to withstand challenge in canaries.⁸ Differential diagnoses include toxins (organophosphates, dimetridazole), trauma, atoxoplasma and bacterial meningoencephalitis (Table 39.8).

HERPESVIRUS

Herpesviruses are much less a clinical problem in Passeriformes than in many other avian orders. Uncharacterized herpesviruses causing necrosis of the liver, spleen and bone marrow have been reported in finches (Estrildidae), canaries and weavers (Ploceidae).⁶⁰

CYTOMEGALOVIRUSES

Cytomegalovirus can cause severe conjunctivitis, pseudosymblepharon (crust sealed eyelids) and acute illness, often with a high mortality rate, in Australian and African finches. ^{17,24,103} Diagnosis is based on histopathology with cytomegaly and karyomegaly of epithelial cells, hemorrhage in the lung and bronchi and diphtheroid lesions in the esophagus and choana. Basophilic intranuclear inclusion bodies within epithelial cells of the conjunctiva and respiratory tract can be observed. ^{17,94} Treatment consists of supportive measures including tube-feeding and keeping the eyelids free of forming crusts. Differential diagnoses of conjunctival lesions include infections with poxvirus, *Chlamydophila*, *Mycoplasma* or other bacteria. ²⁴ For differential diagnoses of sudden death, see Toble 39.7.

PAPILLOMAVIRUS

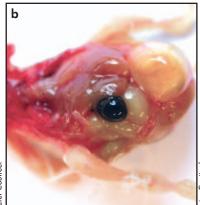

Proliferative wart-like skin masses observed on the legs and feet of Fringillidae (especially siskins [*Carduelis spinus*] and European chaffinches [*Fringilla coelebs*]) are caused by papillomaviruses (Fig 39.22). In other passerine species, however, lesions appear to be rare.⁹⁵

Papillomavirus lesions can bleed profusely and can often cause leg band constriction.¹⁷ Papillomavirus-like infections causing epithelial proliferations at the commissure of the beak and on the head in canaries have been described in Belgium.²⁸ Treatment consists of local disinfection. An autogenous vaccine can be considered, although no data exist to prove the efficacy in Passeriformes.¹⁷ Differential diagnoses include hyperkeratosis, poxvirus, *Knemidokoptes* mites and trauma.

CIRCOVIRUS

A disease called "black spot" by European canary breeders has been proven to be caused by a circovirus. The disease is observed in hatchlings and nestlings and has a high mortality. Signs include abdominal enlargement and congestion of the gall bladder (visible as a black spot through the skin) (Figs 39.23 a-c).¹⁷ Feather loss and lethargy in finches also have been associated with circovirus.⁷⁸ Diagnosis is based on recognizing inclusion bodies on histopathology of the bursa of Fabricius or the presence of 18-nm viral particles on electron microscopy. PCR techniques for psittacine circovirus (psittacine beak and feather disease —PBFD virus) fail to demonstrate viral presence, indicating that the canary circovirus differs genetically from the PBFD virus.⁵² Nucleotide sequencing

showed the virus to be more closely related to the Columbid circovirus than to the PBFD virus.¹¹¹ Differential diagnoses include *Atoxoplasma*, *Isospora*, *E. coli* and other causes of mortality in nestlings (see Table 39.7).

Bacterial Diseases

The general principles for diagnosing, treating and controlling bacterial disease in Passeriformes are similar to those in other avian orders. There is normally no bacterial growth on routine aerobic microbiologic cultures taken from passerines. Stained fecal smears collected from normal canaries and finches reveal either no bacteria or low levels of gram-positive rods or cocci. 17,71

CHLAMYDOPHILA PSITTACI

The causative agent of chlamydiosis is *Chlamydophila psittaci*. ¹¹³ Passeriformes appear to be less susceptible than Psittaciformes to chlamydiosis. ⁷¹ Clinical signs are nonspecific and include general apathy, diarrhea and nasal and ocular discharge. Mortality is usually low. ³²

Diagnosis is normally made at necropsy. Identification of the organism within macrophages in impression smears

Fig 39.24 | This canary has Mycoplasma conjunctivitis.

Fig 39.25 | This breeding female looks dirty and wet and has sweating disease.

of internal organs or air sac walls can be made by use of a Macchiavello, Gimenez or Stamp stain. 113 Antigen may be identified from a swab of the cut surface of internal organs or air sac walls by use of an ELISA or PCR.30,77

For treatment, water-soluble doxycycline hyclate, at a dose of 280 mg/L, has been proven to achieve plasma doxycycline concentrations > 1 μ g/ml in cockatiels. 44,88 Doxycycline hyclate at 280 mg/L in the drinking water and simultaneously 280 mg/kg in soft food are clinically effective for the treatment of chlamydiosis in canaries and finches and cause no side effects. Often citric acid is added to the drinking water. In Europe a pharmaceutical company produces water soluble doxycyclinum hyclatumd in combination with citric acid. This combination makes the product more water soluble and less sensitive to light.

MYCOPLASMA spp.

Mycoplasma spp. are often associated with conjunctivitis and other signs of upper respiratory disease in canaries and finches (Fig 39.24). Epizootic conjunctivitis caused by Mycoplasma gallisepticum has been reported in house finches (Carpodacus mexicanus) in the eastern US.27 Diagnosis is based on PCR or culture of conjunctival swab samples, but isolation of this organism is often difficult.

Treatment with ciprofloxacin ophthalmic solution and tylosin at 1 mg/ml in the drinking water resolved mycoplasma infections in house finches.73 Suspected cases of mycoplasma infections should be treated with tylosin, tetracycline or enrofloxacin.71

Differential diagnoses include Enterococcus faecalis and other bacterial causes of upper respiratory disease (see Table 39.9), Mycoplasma, Atoxoplasma, Isospora, toxins, liver disease, Sternostoma and Macrorbabdus.

GRAM-NEGATIVE BACTERIA

Escherichia coli

E. coli is probably the most important bacterial cause of diarrhea and nestling mortality in canaries and finches. Various other Enterobacteriaceae also can be involved. Apparently healthy adult birds can be carriers of E. coli, resulting in clinical problems during the breeding season.¹⁷ E. coli is a secondary pathogen and should be considered the sequel to a primary problem, such as poor hygiene, unsuitable housing, unbalanced diet or other management-related problems. Primary pathogens such as Atoxoplasma, circovirus or polyomavirus also may be present.32

The typical clinical presentation in a breeding flock includes diarrhea, dehydration and cachexia. The nests as well as the breeding females are dirty, wet and yellowish (sweating disease) (Fig 39.25). The youngsters die before they can be leg-banded on day 6 or 7.17 Diagnosis is based on aerobic cultures of fecal samples or internal organs in septicemic disease.

Treatment consists of antibiotics, chosen on the basis of culture and sensitivity results, and should be administered in drinking water and egg food from one day before hatching until 6 days after hatching. At the same time, other management-related problems must be addressed.17

Differential diagnoses include other bacterial infections that cause diarrhea and mortality, Atoxoplasma, Isospora, polyomavirus, circovirus, Chlamydophila, toxic enteritis and PMV-1.

Salmonella

Salmonella typhimurium is the most commonly isolated Salmonella species in Passeriformes. 47 Salmonellosis is clinically (and at necropsy) very similar to Yersinia

pseudotuberculosis infections.⁵⁹ Many birds will die without preliminary signs, but chronic disease can also occur. The existence of clinically healthy carriers in canaries and finches has not been researched.³² On necropsy, small yellow miliary bacterial granulomas can be observed on a dark and swollen liver and spleen. Sometimes focal necrosis in heart, lung and pectoral muscle can be seen.¹⁷ Diagnosis is confirmed on culture.

Treatment consists of antibiotics chosen on the basis of culture and sensitivity. Antibiotics commonly used include sulfonamid-trimethoprim, enrofloxacin and marbofloxacin. Elimination of salmonellosis is often difficult, and an antibiotic treatment should be combined with counseling on good hygiene and disinfection. The success of a flock treatment should be monitored in serial bacterial cultures at 3 to 6 weeks after therapy by examining pooled fecal samples in enrichment medium.³²

Differential diagnoses of necropsy lesions include *Yersinia pseudotuberculosis* and mycobacterial infections. A large number of viral, bacterial and parasitic pathogens must be considered in the differential diagnoses of the clinical presentation of unspecific disease and flock mortality (see Table 39.7).

Yersinia pseudotuberculosis

Yersinia pseudotuberculosis infects a wide range of avian and mammalian species, including humans. It is particularly common in a variety of passerine species and also in rodents. ⁴⁹ The pathogen is thought to be indigenous to central and northern Europe, but is now diagnosed throughout the world. The disease is most common in autumn, winter and spring months and is believed to be transmitted by rodents and migratory birds. ^{17,47}

The clinical signs are nonspecific but normally include peracute mortality in adult birds.¹⁷ Diagnosis is based on the typical small, yellow, miliary granulomas on a dark and swollen liver and spleen (Fig 39.26) and impression smears and bacteriological cultures revealing gram-negative coccoid rods.⁴⁹ Clinically diseased birds usually die before treatment can be initiated, but the rest of the flock should be treated based on culture and sensitivity. Enrofloxacin has been shown to completely protect canaries from experimental infection with *Yersinia pseudotuberculosis*, whereas groups of canaries treated with doxycycline, chloramphenicol, ampicillin and sulphamerazine-trimethoprim suffered mortality rates between 30 and 44%.⁵³

Differential diagnoses of the typical necropsy lesions include *Salmonella typhimurium* and mycobacterial infections.

Fig 39.26 | Miliary granulomas as seen on this canary's dark and swollen spleen are indicative of Yersinia pseudotuberculosis.

Campylobacter spp.

Campylobacter fetus subsp. *jejuni* is common in tropical finches and canaries. Society finches can be asymptomatic carriers. ^{17,59} Clinical signs include apathy in adult birds and high mortality in nestlings. Diseased birds develop yellow diarrhea and pale, voluminous droppings. ¹⁷ A fecal Gram's stain reveals comma- to S-shaped gram-negative rods. Culture requires special media and a microaerophilic environment. ⁴⁷ Campylobacter are often resistant to multiple classes of antibiotics, and the disease frequently recurs despite antibiotic treatment. ^{47,49} Doxycycline, erythromycin or enrofloxacin could be good choices for flock treatment. ^{17,47} Thorough cleaning and disinfecting of the aviary may help prevent reinfection. ⁴⁹

Pseudomonas spp.

Pseudomonas aeruginosa is the most important pathogen in this genus. Infections often originate from contaminated drinking water, misting bottles or inappropriately prepared sprouted seeds.⁷¹ Clinical signs of disease commonly include foul-smelling diarrhea, but air sacculitis and infections of the oropharynx may also be present. Diagnosis is based on culture, using routine aerobic media.

Treatment is often difficult because *Pseudomonas aeruginosa* is resistant to many antibiotics. Quinolones often offer an adequate treatment.⁴⁷ Effective treatment is based on antibiotics (selected by sensitivity testing) combined with elimination of the source of contamination.³² Differential diagnoses to consider are listed in Tables 39.9 and 39.12.

Other Gram-negative Bacteria

Other gram-negative bacteria such as *Citrobacter*, *Klebsiella*, *Serratia*, *Pasteurella*, *Bordetella*, *Borrelia*, *Actinobacillus* and *Haemophilus* spp. also have been isolated from diseased Passeriformes. ^{49,71}

GRAM-POSITIVE BACTERIA

Enterococcus faecalis

Enterococcus faecalis (formerly Streptococcus bovis) is a frequent inhabitant of the passerine alimentary tract.⁴⁷ It also is associated with chronic tracheitis, pneumonia and air sacculitis.25 Affected birds have increased respiratory sounds, voice changes and dyspnea. Form canaries are especially sensitive. Treatment with antibiotics will improve the clinical signs, but individual birds can seldom be completely healed. Differential diagnoses include Sternostoma tracheacolum, other bacterial infections of the upper respiratory tract, poxvirus, PMV-1, Chlamydophila, Aspergillus, Atoxoplasma, and Trichomonas and causes of abdomen distension (Table 39.10). Concurrent infections with Enterococcus faecalis and Sternostoma tracheacolum (tracheal mites) can occur.

Mycobacterium spp.

Mycobacterial infections were the most commonly diagnosed bacterial diseases in a review of 546 necropsies performed between 1991 and 1997 in Passeriformes in Switzerland. Over 8% of all necropsied Passeriformes suffered from a mycobacterial infection, and 40% of all diagnosed bacterial infections in this avian order were caused by Mycobacterium spp.1

Clinical signs are nonspecific but include chronic "sick bird", diarrhea, weight loss and death.36 The classic disease with tubercles in the organs is seldom seen in Passeriformes. These results suggest that mycobacterial disease is often overlooked in passerine necropsies. Acid-fast-stained impression smears of the intestinal wall and liver should be performed on every necropsied passerine.1 Although classically described as being caused by Mycobacterium avium, the advent of PCR techniques for species identification has (at least in Europe) shown Mycobacterium genavense to be the most commonly isolated species. 56,57,83,86,90,100,110 Mvcobacterium tuberculosis has recently been diagnosed in a canary.55

In Passeriformes, mycobacterial infections are almost exclusively diagnosed postmortem. Gross necropsy is often unrewarding, with nonspecific hepato- and splenomegaly and thickened intestinal walls. Acid-fast bacilli can, however, be found in the eyelids and many internal organs including liver, jejunum, ceca and/or colon, spleen, lung, air sac, iris, brain, bone marrow, muscle and kidney. 57,83,100 No treatment of mycobacterial diseases in Passeriformes has been described.

Other Gram-positive Bacteria

In addition to the gram-positive species described above, infections with Erysipelothrix rhusiopathiae, Listeria monocytogenes, Clostridium perfringens, as well as various Stapbylococcus spp. and Streptococcus spp. have been described in Passeriformes.71

Fungal Diseases

MACRORHABDOSIS

Classically known as a common disease in budgerigars ("going light"), this organism was previously termed "megabacteria" or "avian gastric yeast". Observation has been made of this organism in a wide range of passerine species. ^{23,50,43,84} Historically described as "megabacteriosis" during the last 20 years, there has been frequent debate on the description of this as a large gram-positive bacterium. Recent investigations in Germany proved that the so-called megabacteria are indeed fungi, ^{91,92} and Phalen has now renamed the pathogen, *Macrorhabdus ornithogaster*.

Clinical Disease

Chronic depression and weight loss are typical of macrorhabdosis. Birds are always hungry and stay close to the food bowl, eating large quantities of soft food. Regurgitation is not a clinical sign in passerines. Droppings often contain undigested seeds. The patient may be anemic with pale muscles. The liver becomes visible due to the proventricular dilatation. Other diseases that either may have triggered macrorhabdosis or developed as secondary diseases following macrorhabdosis must be considered.

Diagnosis

Diagnosis is based on microscopic examination of a fecal sample. The organism is easily recognized on a wet mount or following a Gram's stain using a 1000 magnification^{17,50} (Fig 39.27). Failure to find Macrorhabdus organisms does not prove that the bird is not infected,

as shedding begins only after a certain stage of disease and then may occur irregularly. Microscopic examination of sequential fecal samples will increase the sensitivity. Pooled fecal samples from an aviary will give good information on the status of infection within a group of birds. The organism appears in proventricular scrapings after necropsy. Note that routine fungal culture will not yield growth of this fastidious organism.

Necropsy

A distended, thick-walled proventriculus, often with white mucus on the mucosal surface, is revealed upon necropsy (Fig 39.28). Sometimes, ulcerations and small petechial bleedings of the mucosa can be detected.

Prophylaxis and Treatment

Traditional therapy consists of supportive care, including a warm, controlled environment and administration of amphotericin B. Antibiotics for secondary infections can be given. The patient should have access to soft food ad libitum. Concurrent diseases should be treated accordingly.

Differential Diagnoses

Chronic bacterial infections such as mycobacteriosis and *Chlamydophila* as well as parasitic infections such as *Atoxoplasma*, *Isospora*, and *Cochlosoma* may be suspected. Toxins and nutritional changes should also be considered.

CANDIDIASIS

Candida is a common environmental contaminant and in low numbers is considered a normal inhabitant of the

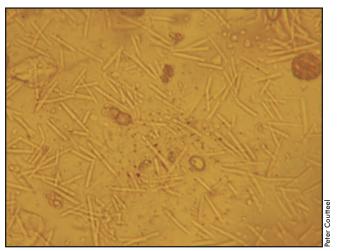

Fig 39.27 | Macrorhabdus (400x, unstained) is easily recognized on a wet mount or following a Gram's stain.

Fig 39.28 | Macrorhabdosis, distended proventriculus, is shown in this canary.

gastrointestinal tract. ^{59,115} It is considered an opportunistic pathogen. Predisposing factors include prolonged antibiotic therapy, malnutrition, spoiled food, hand feeding, stress (crowding) and the juvenile immune system. ¹⁷ Disease is not overly common in Passeriformes but is observed more often in tropical finches than in canaries. ³² Clinical signs include regurgitation, anorexia, diarrhea, whole seeds in the feces, crop stasis, gas formation and tilted appearance with elevation of the abdomen and tail. ¹⁰⁸ Diagnosis is based on demonstrating large numbers of budding yeast, which can be visualized on a crop swab or in a fecal sample. At necropsy, a thickened crop wall and white coating of the mucosa, as well as possible white plaques in the oropharynx, can be observed.

Prophylaxis and Treatment

Prophylaxis is based on prevention of predisposing factors (listed above). Treatment may include antimycotic drugs, such as nystatin (not absorbed from the gastrointestinal tract), fluconazole or ketoconazole (systemic drugs). Medicated drinking water and soft food may be offered. ¹⁷ Differential diagnoses include *Trichomonas*, poxvirus, bacterial stomatitis, ingluvitis or enteritis, macrorhabdosis and hypovitaminosis A.

ASPERGILLOSIS

Aspergillosis is one of the most commonly diagnosed diseases in mynahs.^{58,62} It is occasionally diagnosed in canaries and finches. Predisposing factors include a warm and humid environment, overpopulation and contaminated food and environment. Recently imported birds are especially susceptible.

Clinical Disease

Mynahs may experience loss or change of voice, peracute dyspnea caused by a syrinx granuloma, chronic dys-

pnea and depression. In finches, aspergillosis is an acute disease with respiratory distress.¹⁷

Diagnosis

Definitive diagnosis of aspergillosis in a live bird is difficult. Diagnostic procedures in mynahs may include tracheoscopy, endoscopy and culture of suspicious lesions.

Necropsy

Typical aspergillosis lesions within the lung and air sac walls and syrinx granulomas may be seen. Culture, Gram's stain, wet mount or histopathology can provide a definitive diagnosis.

Prophylaxis and Treatment

Concentration of Aspergillus spores in the environment (moldy fruits on bottom of cage, general poor hygiene) should be reduced as well as susceptibility of the bird by providing a balanced diet (ensuring adequate vitamin A, in particular), improving the room climate, increasing ventilation and reducing stressors. Treatment consists of giving antimycotics orally and via inhalation, as in psittacines.

Differential Diagnoses

Iron storage disease and other causes of respiratory disease in mynahs (see Table 39.9) and dyspnea due to abdominal enlargement (see Table 39.10) must be considered.

DERMATOMYCOSES

The most common etiologic agents are *Microsporum gallinae* and *Trichophyton* spp.⁷¹ Clinical signs include feather loss and hyperkeratosis predominantly on the head and neck (Figs 39.29, 39.30).¹⁷ Diagnosis is based on culture or biopsy and histopathology. Treatment with topical miconazole or several sprays with enilconazole

Fig 39.29 | Dermatomycosis is shown on this canary's head.

Fig 39.30 | Dermatomycosis is shown on the dorsal surface of this canary's wing.

are effective. Systemic antimycotics will provide improvement but probably not eliminate the infection. Differential diagnoses include *Knemidokoptes* mites, bacterial dermatitis, feather picking, cannibalism and hyperkeratosis (Table 39.11).

Parasitic Diseases

COCCIDIAL DISEASES

Atoxoplasma

The taxonomy of *Atoxoplasma* spp. is controversial. Some authors suggest that this genus should be placed in the *Isospora* genus. ^{68,114} This disease is also called "Lankesterella" or "big liver disease". ¹⁷ *Atoxoplasma* spp. appear to be host specific. ⁶⁸ The species affecting canaries has been named *Atoxoplasma* or *Isospora serini*. ^{17,32}

Unlike other Eimeriidae species, the asexual life cycle of Atoxoplasma takes place in internal organs and not in the intestinal mucosa.⁵⁹ The life cycle of the organism begins with the host's oral ingestion of oocysts.⁸¹ Oocysts excyst the sporozoites within the intestinal tract. Sporozoites penetrate the intestinal wall and spread in lymphocytes and macrophages to parenchymal organs. Affected organs include lung, liver, spleen, pancreas, pericardium and intestinal epithelium. Several generations of asexual schizogony in these organs produce merozoites. Merozoites migrate back to the intestinal mucosa. Gametogony (sexual cycle) of the merozoites produce oocysts. Oocysts are excreted with the feces.

This is a common flock disease in canaries but only occasionally diagnosed in exotic finches. It has been a devastating disease for the captive population of the endangered Bali mynah (*Leucospar rothschildi*). 79,81,114

Clinical Disease

Typically, this is a disease of young canaries aged 2 to 9

months.³² The affected bird will appear fluffed up and will be debilitated and anorectic. It will have diarrhea and a red, swollen vent. Hepatomegaly is visible through the abdominal wall caudal to the sternum. Mortality is variable, but up to 80%.³² Occasionally, a patient will exhibit neurologic signs, such as epileptiform seizures and intermittent weakness. It may exhibit respiratory distress.^{5,121}

Diagnosis

Definitive antemortem diagnosis is difficult because after the acute phase, only a few *Atoxoplasma* oocysts are excreted. Pecal flotation shows oocysts with 2 sporocysts, each containing 4 sporozoites. Microscopic differentiation from Isospora is not easy: *Atoxoplasma serini* oocysts = $20.1 \times 19.2 \, \mu m$, *Isospora canaria* oocysts = $24.6 \times 21.8 \, \mu m$. A PCR assay^c has been developed that will detect an 18S rDNA fragment of *Atoxoplasma* species in feces, blood and tissues of infected birds. 68

Necropsy

Necropsy reveals severe splenomegaly, hepatomegaly and dilated bowel loops.¹⁷ Intracytoplasmic inclusion bodies will appear in mononuclear cells in impression smears or on histopathology of the lung, liver and spleen.^{5,17,72}

Prophylaxis

Sound husbandry practices must be observed: avoid overcrowding, practice good hygiene and provide proper nutrition.⁸¹ Newly acquired birds must be quarantined and screened with multiple fecal flotations for the presence of *Atoxoplasma*. Adult canaries can be asymptomatic carriers and will shed oocysts sporadically. In collections with recurrent disease, consider annual coccidial treatment prior to the breeding season.

Treatment

Clinically diseased individuals usually die before they respond to treatment. Anticoccidial drugs such as toltrazuril, sulfachloropyridazine (Esb3 30%) or other sulfonamides may be given. Atoxoplasmosis is considered resistant to treatment; however, Esb3 30% at 150

mg/L of drinking water 5 days a week every week from the moment of diagnosis until after molting has proven to stop production of oocysts, although it will not influence the intracellular stages.³²

○ Seldom

Occasional

Differential Diagnoses

E. coli, mycobacteria and other bacterial pathogens, *Isospora, Macrorhabdus, Chlamydophila*, polyomavirus, circovirus and toxins must be considered as differentials.

Isospora

★ Common

The life cycle is completed in the intestinal tract (unlike atoxoplasmosis but like all other Eimeriidae species). Species-specific *Isospora canaria* is common in canaries.

Isolates from over 50 species of passerines other than canaries represent different *Isospora* species.¹⁷ Clinical signs are diarrhea and emaciation (Fig 39.31)³² as well as dilated bowel loops causing abdominal distension. *Isospora* does not always cause clinical disease.

Diagnosis is based on large amounts of oocysts observed on fecal flotation, which, unlike in atoxoplasmosis, are secreted on a continuous basis. Treatment with anticoccidial drugs will be more successful than against *Atoxoplasma* spp. Differential diagnoses include *Atoxoplasma* spp., *E. coli*, mycobacteria, *Macrorhabdus*, other enteric bacteria, toxic enteritis and sudden nutritional change (Table 39.12).

Fig 39.31 | A canary presented with coccidiosis had emaciation and abdominal swelling.

Cryptosporidium

The clinical significance is not fully understood, but cryptosporidiosis appears to be emerging as a serious disease threat in many avian species, including canaries and finches. 17,81 Autoinfection can occur because of the endogenous sporulation. It may infect and cause disease in the mucosal epithelial cells of the gastrointestinal, respiratory and urinary tracts. The very small oocysts $(4 \times 8 \mu m)$ with 4 sporozoites can be found in fecal flotations. The small size and low numbers of excreted oocysts make diagnosis difficult. Additional diagnostic methods include acid-fast staining, direct immunofluorescence staining or ELISA of fecal samples. Differential diagnoses include other causes of gastrointestinal (see Table 39.12) and respiratory (see Table 39.9) disease.

Sarcocystis

Sarcocystis spp. have an obligatory two-host life cycle. The definitive host is the opossum, whereas a wide variety of avian species can be intermediate hosts. In addition, cockroaches, rats and flies can serve as transport hosts. In the avian intermediate host, merozoites enter striated muscle, where they can be observed macroscopically. Clinical signs can range from inapparent infection to anorexia, diarrhea, weakness, dyspnea, ataxia and death. Diagnosis is based on demonstrating sarcocysts on histopathology of muscle biopsies or after necropsy.

Toxoplasma

Cats and other felids are the only definitive hosts for *Toxoplasma gondii*. Essentially, any warm-blooded animal can be infected as an intermediate host by ingestion of oocysts excreted by cats. Most infections in birds are subclinical and asymptomatic.⁸¹ In the acute phase of infection, birds may show severe respiratory signs.⁵⁹ In chronic infections, typical signs include blindness, ataxia and torticollis.^{32,67,116} Antemortem diagnosis is difficult

and based on an increasing antibody titer. Prevention is based on eliminating direct and indirect contact with cats. Treatment described includes pyrimethamine at 0.5 mg/kg orally every 12 hours for 14 to 28 days or diclazuril at 10 mg/kg orally every 24 hours on days 0, 1, 2, 4, 6, 8 and 10.59 Differential diagnoses include other causes of central nervous system signs (see Table 39.8).

FLAGELLATE DISEASES

An unidentified flagellate found in the crop has been described as a possible cause of a dermatologic disease in canaries. Clinical signs include feather loss on the crown and neck, often accompanied by signs of dermatitis.¹⁶

Cochlosoma

Motile flagellates found in the feces of finches have been identified as *Cochlosoma* sp. or *Cochlosoma anatis*-like protozoa, which are classically transmitted by asymptomatically infected society finches, often used as foster parents. ^{17,42,87} Most commonly affected species include red-headed parrot finches, Bengalese and Lady Gouldian finches. ⁴²

Clinical Disease

Adult birds are usually asymptomatic carriers. Disease most commonly affects young birds from 10 days to 6 weeks of age.³² Clinical signs include dehydration, diarrhea, whole seeds in the droppings, yellow staining of nestlings due to contact with their droppings, or death.

Diagnosis

Diagnosis requires demonstration of motile flagellates in saline smears from fresh warm feces. ¹² Cochlosoma are smaller than giardia and hard to find in a fecal exam. They can be detected histologically in the intestinal wall (JMM Cornelissen, personal communication).

Prophylaxis and Treatment

All newly introduced adult finches should be screened via fresh fecal smears and, if necessary, treated during quarantine. All breeding finches should be screened and treated, especially foster parents, prior to breeding. Ronidazole can be administered at 50 mg/L drinking water and at 50 mg/kg in soft food for 7 days. ¹⁷ Dimetridazole (100 mg/L drinking water for 5 days) may also be helpful. Overdosage of dimetridazole or metronidazole results in reversible CNS signs. Treatment often involves an antibiotic for secondary intestinal infections.

Differential Diagnoses

Differential diagnoses include *Isospora* and other enteric parasites (see Table 39.12), *E. coli*, and other bacterial infections that cause diarrhea and juvenile mortality, *Macrorbabdus* and toxic enteritis.

Trichomonas

Infections with *T. gallinae* are seen sporadically in canaries and finches. ^{12,32} Birds of all ages can be affected, but the infection is most predominant in younger birds. Clinical signs include respiratory changes, regurgitation and emaciation. Trichomoniasis can cause thick, yellow caseous lesions of the infraorbital sinus. ⁶⁶ Diagnosis is based on a fresh wet mount of a crop swab. At necropsy, a thickened opaque crop wall with plaque development is noted (Fig 39.32). Imidazoles are used for treatment as for *Cochlosoma* spp. Differential diagnoses include poxvirus, *Candida* and other causes of respiratory signs (see Table 39.9).

Giardia

Giardia has also been reported in association with gastrointestinal disease in Passeriformes.⁷¹

BLOOD PROTOZOA

Protozoa are regularly observed in blood smears of clinically healthy captive and free-ranging Passeriformes

species and are occasionally associated with primary disease. The most commonly encountered blood protozoa include *Plasmodium* spp., *Hemoproteus* spp., *Leucocytozoon* spp., *Trypanosoma* spp. and *Piroplasma* spp.

MICROSPORIDIA

Encephalitozoon bellem has been diagnosed in a variety of avian species from different orders. Although it has not yet been described in Passeriformes, there is no reason why it should not infect birds of this order.¹¹

NEMATODES

Syngamus trachea (Gapeworm or Red Worm)

Syngamus trachea is common in Sturnidae (starlings) and Corvidae (crows) and must be considered in all Passeriformes housed in outdoor aviaries. The life cycle is direct, but earthworms can act as transport and accumulation hosts. Adult worms live in permanent copulation within the lumen of the trachea.¹⁷

Fig 39.32 | An oral probe is passed down the opened esophagus in this canary with trichomoniasis. The canary has a thickened crop wall with plaque development.

Fig 39.33 | *Syngamus trachea* (gapeworm or red worm) is shown in a canary's opened trachea.

Clinical Disease

Respiratory distress, gasping, coughing or sneezing is commonly observed in affected birds.¹⁷ Head shaking and dried blood at the beak commissure may also be observed.

Diagnosis

Tracheoscopy or tracheal transillumination reveals adult worms (Fig 39.33). Fecal flotation will reveal ovoid eggs (70 to $100 \, \mu m \times 43$ to $46 \, \mu m$) with a thick operculum at each pole similar to eggs of *Capillaria* spp. The number of excreted eggs does not correlate with the presence or severity of clinical signs.

Prophylaxis and Treatment

All newly introduced birds must be quarantined and screened by fecal flotation and, if necessary, treated. Contact with natural soil and earthworms must be prevented. A regular annual or biannual worming program should be instituted. Oxygen supplementation should be considered, and dexamethasone administered intratracheally or intramuscularly may be needed to reduce inflammation and mucosal swelling. If size allows, adult worms can be removed with an endoscope and biopsy forceps. Flubendazole, fenbendazole or ivermectin can be used to kill the adult worms that will then be coughed up or swallowed.

Differential Diagnoses

Differential diagnoses include *Sternostoma trachea-colum*, *Chlamydophila psittaci*, *Mycoplasma* spp., bacterial rhinitis, tracheitis, pneumonia, aspergillosis, *Trichomonas* spp., *Cryptosporidium* spp. and causes of abdominal distension.

Spiruroidae

Acuaria spp. and *Geopetitia* spp. are most commonly described. 46,64,68 Development proceeds via arthropodal intermediate hosts, such as cockroaches, crickets and

mealworm beetles. 46 In the bird, Spiruroidae inhabit the proventricular and ventricular mucosa under the koilin lining. 17 There are no typical clinical signs beyond general malaise and increased mortality. Diagnosis is based on fecal flotation. On necropsy, inflammation of the proventricular and ventricular mucosa is noted. Adult spirurids can be observed under the koilin lining of the ventriculus. Spiruroidae are difficult to treat, with ivermectin most likely to be effective. Differential diagnoses include chronic bacterial enteritis, macrorhabdosis, proventricular candidiasis, coccidiosis, *Cochlosoma* spp. and other helminths.

Other Nematodes

Ascaridia spp. and Capillaria spp., commonly observed in Psittaciformes, are of less significance in canaries and finches. Capillaria spp. are not only found in the intestines but can also inhabit the oropharynx and crop, causing white plaques. Filarial nematodes, such as Serratospiculum spp., Diplotriaena spp. and Splendidofilaria spp., have been reported in Passeriformes. Most infections are not associated with clinical disease.⁷¹

CESTODES

All tapeworms require arthropods as intermediate hosts and are most common in finches (eg, parrot finches) that are fed live food. 17,71 Many different species have been described, but in most cases they cause no clinical disease. 71 Clinical signs of disease include emaciation, diarrhea and debilitation. Proglottids or eggs can be demonstrated in fecal flotation samples, but excretion is irregular. Prophylaxis includes limiting access to intermediate hosts and using insect-proof screening. Treatment with praziquantel can be effective.

Fig 39.34 | Tracheal mites (*Sternostoma* spp.) are seen as small black dots in this opened trachea.

Fig 39.35 | Red mites (*Dermanyssus gallinae*) are shown in the dampened feathers of this canary.

TRACHEAL MITES

Sternostoma tracheacolum should be called tracheal mites and not air sac mites because the mites are normally present in the trachea and syrinx.⁷¹ Common in Lady Gouldian finches and other exotic finches, they are less common in canaries.¹⁷

Clinical Disease

Clinical signs include wheezing, gasping, open-mouthed breathing, head shaking, loss of voice, cessation of singing and respiratory distress. Mortality is low.

Diagnosis

Tracheal illumination after wetting the feathers may show the mites, recognized as small black spots, in the lumen of the trachea. Lack of visualization does not rule out their presence.¹⁷ The use of the 1.2 mm endoscope is possible, even in the unanesthetized patient. The authors warn that the inexperienced practitioner may kill the bird with this procedure, either by puncturing the trachea or suffocating the bird.

On necropsy, mites can readily be recognized macroscopically within the opened trachea (Fig 39.34).

Prophylaxis and Treatment

Prophylaxis is difficult, as recognition of carriers with a low burden is not possible. One should consider treating all newly acquired birds during quarantine. Individual birds can be treated with ivermectin or doramectin. Ivermectin or doramectin can be diluted with 1:10 with propylene glycol or sesame oil, respectively. The drug is applied as a "spot on" to the bare skin dorsolateral to the thoracic inlet (at the site of jugular blood collection), at the rate of 1 drop per bird up to 50 g and repeated after 7 to 10 days. The potential of propylene

glycol toxicity can be avoided by using doramectin that contains sesame oil. It may be helpful to hang a dichlorvos strip near (but out of reach of) the birds.¹⁷

Differential Diagnoses

For differential diagnoses, consider *Enterococcus faecalis* and other bacterial causes of upper respiratory disease, poxvirus, *Chlamydophila*, *Atoxoplasma*, *Trichomonas*, *Aspergillus* and *Syngamus* (see Table 39.9).

SCALY MITES

Knemidokoptes pilae cause hyperkeratotic lesions on the feet and the base of the beak.¹⁷ Pruritus is noted only by attentive owners. Diagnosis is based on recognizing the small bore holes within the hyperkeratotic lesions or demonstrating the scaly mites in scrapings of the lesions. One may treat locally with plant oil to suffocate the mites in conjunction with ivermectin "spot on". Differential diagnoses include hyperkeratosis, dermatomycoses, papillomavirus, fiber constriction or poxvirus (see Table 39.11).

BLOOD-SUCKING MITES

Dermanyssus gallinae (red mites) hide in nests and other dark areas in the aviary and attack the birds only at night¹⁷ (Fig 39.35). Ornithonyssus sylviarum (northern or fowl mite) spends its entire life cycle on the host.³² This mite can cause high mortality, especially in nestlings. Clinical signs include general depression, anemia, respiratory distress and pruritus. Diagnosis is based on recognizing the mites on the bird or in nests or under perches. The dark excrement of the mites can be found under the nests. During hot weather, the mite population can explode within days. Preventive measures should be initiated before the breeding season. New

Fig 39.36 | Feather mite (Analges spp., Megninia spp.) eggs (nits) are shown in the tail feathers of a canary.

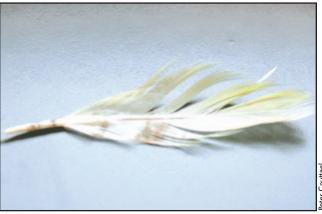

Fig 39.37 | The effects of quill mites (*Syringophilus* spp., *Dermoglyphus* spp.) are fault lines and hemorrhages in the feather's shaft.

nests and perches should be installed and the breeding cages thoroughly cleaned. In aviaries with a known history of red mites, prophylactic use of an insecticide prior to the breeding season may be considered.

The birds may be dusted with a permethrin or carbaryl powder using a salt shaker or sprayed (along with the environment, including the nesting material) with a dilution of carbaryl (5 g 85% carbaryl powder/L water). Fipronil is also effective and well tolerated. Following application of any insecticide, the cage or room should be vacated and thoroughly cleaned with nests and perches replaced with new ones.

OTHER ECTOPARASITES

Quill mites, epidermotic mites (Fig 39.36), and lice of a variety of species have been described in Passeriformes.^{32,71} These mites cause general nervousness and feather damage. Quill mites are a major problem for exhibition birds.¹⁷ Many flight and tail feathers develop horizontal lines and hemorrhages in the shaft (Fig 39.37). Diagnosis can be made by opening the base of the shaft of a growing feather and detecting the parasite microscopically. Discovery should cause the owner to rethink general hygiene and management practices. Treatment is similar to that used for blood sucking mites.

Metabolic Diseases

IRON STORAGE DISEASE

Together with aspergillosis, iron storage disease is the most common disorder diagnosed in mynah birds. 1,62 Passerine families with higher incidence of iron storage disease include starlings (Sturnidae), tanagers (Emberizidae), bulbuls (Pycnonotidae) and birds of paradise (Paradisaedae). 36 (Toucans [Rhamphastidae] are not

Passeriformes but belong to the order Piciformes and are also commonly diagnosed with iron storage disease).

Various theories exist concerning the pathogenesis of iron storage disease. High iron absorption from the intestines, regardless of body iron stores (similar to hereditary hemochromatosis in humans) is one possibility.⁷⁵ High or toxic levels of iron in the diet may be a cause or contributing factor.²¹ The incidence of iron storage disease in mynahs has, however, not decreased despite the development of controlled-iron diets. Ascorbic acid in citrus fruits and green leafy plants may enhance the bioavailability of iron; thus, high levels of ascorbic acid (vitamin C) in the diet of captive birds may be a factor.4 Iron storage disease can, however, also develop in birds specifically fed a diet lacking citrus fruits. Lack of substances such as tannin in the diet of captive birds compared to the high tannin content of water in the rain forests is another possibility. Tannin acts as a natural mineral chelating agent and therefore decreases the bioavailability of iron in the intestinal tract. 119 Concurrent disease conditions could be responsible for the degree and nature of the pathologic changes described in cases of iron storage disease. In avian species not classically considered predisposed to iron storage disease, such as psittacines, the disease is observed histologically in many individuals that succumb to a concurrent disease.14

Clinical Disease

Clinical signs include abdominal swelling due to ascites and hepatomegaly, dyspnea due to abdominal swelling, apathy and cachexia, loss of intense coloring of beak and periocular skin in mynahs and sudden death.

Diagnosis

Definitive diagnosis is possible only by histopathology of a liver biopsy sample or quantitative determination of the hepatic iron concentration.¹⁵ It is important to know

the species of a diseased patient. Radiography will show hepatomegaly with or without ascites. Values of liver enzymes, such as AST, LDH and AP as well as bile acids, can be increased. Many mynahs will develop a hypoproteinemia.62 Total serum iron and total iron binding capacity do not correlate with the presence or degree of iron storage disease in rhamphastids.118

Necropsy

A swollen liver with an orange-brown or marbled appearance and transudate within the abdomen may be observed on necropsy. On histopathology, deposition of iron pigment may be seen in hepatocytes and hepatic Kupffer cells, as well as in the spleen, gut wall, myocardium, kidney and pancreas.

Prophylaxis and Treatment

A low-iron diet with less than 60 to 100 ppm (mg/kg) of iron should be fed. 119 Food items containing ascorbic acid, such as citrus fruits, should not be offered, while tannin-rich tea such as oak bark tea may be used to replace drinking water several days a week.

Acute respiratory distress and apathy due to ascites must be relieved by abdominocentesis. Consider diuretics to help resolve ascites. In stable patients, phlebotomies at the rate of 1% of the bird's body weight may be performed once a week. This should induce mobilization of hepatic iron for erythrocyte production. Deferoxamine at 100 mg/kg SC q24h over a 4-month period has been proven to normalize the liver iron concentration in toucans. 15 General supportive liver therapy should be considered, using phytotherapeutics such as dandelion, milk thistle or artichoke, possibly in combination with lactulose (see Chapter 4, Nutritional Considerations).

Differential Diagnoses

Differential diagnoses include Aspergillus and other causes of respiratory distress in mynahs (see Table 39.9) and primary hepatic or cardiac disease. For other causes of abdominal distension (see Table 39.10).

OTHER METABOLIC DISORDERS

Amyloidosis of the liver can be observed on necropsy and histopathology of finches such as Lady Gouldian finches.⁷¹ Hepatic lipidosis can be observed in canaries and finches fed a high-fat diet and lacking exercise.

Visceral gout due to hyperuricemia secondary to renal disease is a regular necropsy finding. Diseased birds may show signs of polyuria/polydipsia and apathy, but the most common clinical sign is sudden death. Articular gout is less commonly diagnosed in Passeriformes than

in psittacines.

Skeletal malformation caused by hypovitaminosis D, in conjunction with calcium and phosphorus deficiency or imbalances, can be observed in Passeriformes as in all other avian species.

Toxic Diseases

INHALANT TOXINS

Canaries and finches are particularly susceptible to inhalant toxins because they exchange more air per gram of body weight than do larger birds. Dangers include carbon monoxide exposure (cages in car garages, leaks from gas heaters), overheated polytetrafluoroethylene (non-stick cookware), carpet freshener,²⁹ hair spray, glues, paints and smoke. Disinfectants used in the breeding cages, such as formaldehyde, also pose a hazard. Necropsy reveals nonspecific pulmonary congestion, pulmonary edema and/or hemorrhage (Fig 39.38). Diagnosis is based on a careful history of the bird and its environment.

PLANTS

Plant toxicoses are rare. The majority of ingested plants will merely cause mild gastrointestinal signs. Plants that have proven to result in toxic reactions in canaries include avocado (Persea americana), dieffenbachia (Dieffenbachia spp.), foxglove (Digitalis pupurea), lupine (Lupinus spp.), oleander (Nerium oleander) and yew (Taxus media).2

PESTICIDES

Organophosphates inhibit acetylcholinesterase and cause clinical signs such as anorexia, diarrhea, ataxia, tremors and seizures.^{3,7} The main source of organophosphates is the inappropriate use of insecticides that are used to combat ectoparasites, such as insecticide spray with an alcohol base administered directly on the bird, insecticide spray used in the nest pans and the addition of insecticide strips to the cage.

PHARMACOLOGIC AGENTS

Many drugs used at doses higher than recommended will cause toxicity in passerines as in other avian species. Drugs with a low therapeutic range that can easily induce signs of toxicity (neurologic signs) in canaries and finches include dimetridazole and furans. 40

Fig 39.38 | A canary presented with PTFE (polytetrafluoroethylene) intoxication had acute erythema and edema of lungs (L).

Fig 39.39 | A feather cyst (arrow) is shown in a canary.

Selected Miscellaneous Diseases

NEOPLASTIC DISEASES

Passeriformes have a low incidence of tumors compared to other avian orders.⁷¹ Reported neoplasms include tumor-like pox lesions,³⁸ leukosis in canaries⁷¹ and thymoma in a finch.⁶⁵

FEATHER CYSTS

Feather cysts are common in heavily feathered canaries (Norwich, crest and crestbred) and new color canaries.¹⁷ Due to the histologic features, it has recently been suggested that feather cysts in canaries should be considered benign tumors, and the name "plumafolliculoma" has been proposed. 122 The condition appears to be hereditary but other factors may be involved. The most common localizations include the wings (Fig 39.39), on the back, in the shoulder region and on the chest. The cysts can occur individually or in multiple locations. Depending on the stage of the molt, the cysts will contain blood and gelatinous material or dry keratinous material.¹⁷ Individual cysts can be lanced and curetted but will likely recur. A better option is the surgical removal of the entire cyst.⁷¹ Typically, a hemostat is placed at the base of the cyst. The entire cyst is then removed using a radiosurgical unit. Minimal bleeding is controlled using a ferric subsulfate stick or tissue glue. If necessary, a few stitches can be placed. This procedure works well for cutaneous cysts but fails in wing cysts because the origin of the cyst is the germinal epithelium at the base of the feather follicle. On the wing, this occurs at the insertion on a bone.

CHRONIC ULCERATIVE DERMATITIS (CUD)

Chronic ulcerative dermatitis (CUD) is regularly observed in mynahs. 62 The etiology is unknown, but possibilities include metabolic diseases of the liver, malnutrition, polyomavirus, bacterial dermatitis, fungal dermatitis, lipoma, squamous cell carcinoma and giardiasis. Clinical disease is similar to CUD observed in *Agapornis* spp. and budgerigars. It is most common in the axillary body region, but the entire trunk and upper legs can be affected. It is normally pruritic. Treatment is frustrating and includes controlling secondary bacterial and fungal infections, using collars, improving diet and controlling pruritus with local anesthetics or local phytotherapeutic agents such as calendula gel. Adding an antiseptic, such as chlorhexidine in glycerol, to the bath water can help control secondary infections.

FIBER CONSTRICTION OF THE EXTREMITIES

The fibers derived from nesting material are a common cause of digital swelling, inflammation and necrosis of extremities in canaries and finches. Swelling of the feet and legs should be examined using magnification and a good light source to determine if fibers are involved. Fibers should be cut using a pointed scalpel blade or a 26- to 30-gauge needle, and the incisions should be made parallel to the long axis of the legs. Necrotic or mummified digits must be amputated. Hemorrhage is a complication after removal. Local antibiotics and bandaging may be applied.

HYPERKERATOSIS OF THE EXTREMITIES

Hyperkeratosis, which is common in canaries (Fig 39.40), may be caused by genetics (soft feather breeds),

old age, malnutrition and hormonal imbalances.³⁶ Treatment consists of softening and removing the hyperkeratotic lesions with water soluble creams and addressing predisposing factors, such as malnutrition, and removing leg bands. The differential diagnoses include Knemidokoptes mites and papillomavirus-induced warts.

CONSTRICTIONS OF THE EXTREMITIES

Possible causes of constriction of the extremities include leg bands that are too small, hyperkeratosis, swelling due to trauma or inflammation, Knemidokoptes mites or pox lesions.¹⁷ Bands may be removed by application of oil and then gentle removal using a special leg band scissors or the drill of a dental unit. The primary disease is treated as necessary.

OTHER DISORDERS OF THE **EXTREMITIES**

Other disorders of the extremities may include frostbite, injury from wire netting or burns (eg, from hot stove plates, candles or heaters). Missing toenails or toes (bitten off by small psittacines kept in mixed aviaries or overgrown toenails that become entrapped) are common.

EGG BINDING

Pathogenesis and predisposing factors to egg binding are the same as in other avian species. Clinical signs include fluffed-up appearance of a female bird during the breeding period or a female bird sitting continuously in the nest or on the bottom of the cage. The egg can normally be palpated but definitive diagnosis is based on radiology. Conservative treatment, consisting of stabilization of the patient in a warm, humid environment, subcutaneous infusions, parenteral calcium, and PGE_{10r2} applied to the cervix may lead to spontaneous laying of the egg. If this does not occur, manual removal of the egg should be considered as soon as the bird is stable.

Procedure

The bird is induced with isoflurane anesthesia and placed in dorsal recumbency (being cognizant of the increased respiratory effort often present in the eggbound patient). Warmed lubrication jelly is infused into the cloaca using a 2-ml syringe and a cow teat cannula. Careful digital pressure is applied until the egg can be visualized at the vagino/cloacal junction through the vent. More lubrication jelly is applied between the mucosa of the vagina and the eggshell. The ovocentesis is performed using a 5-ml syringe and an 18-gauge needle. Negative pressure is applied via the syringe at the same time the egg is collapsed by digital pressure through the abdominal wall. Constant, caudally directed

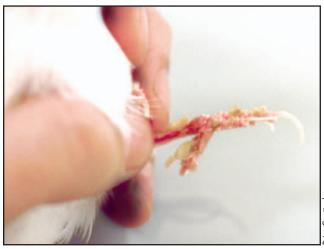

Fig 39.40 | Hyperkeratosis is shown in the feet of a canary.

digital pressure is applied so the collapsed eggshell can be visualized through the cloaca. Lubrication jelly is continually applied as necessary. Using hemostats, the collapsed eggshell is grasped, and the entire collapsed egg is gently removed. This is normally possible because the broken eggshell is still attached to the shell membrane. Any additional eggshell fragments are removed as necessary. Although this procedure can cause small lacerations, it is still considerably less traumatic than a surgical cesarean. Recovery in a warm humid environment is usually rapid and uneventful.

OTHER DISEASES OF THE FEMALE REPRODUCTIVE TRACT

Other disorders of the female passerine may include prolapse of the oviduct, excessive egg laying, salpingitis or egg-related peritonitis.

CONCUSSIVE HEAD TRAUMA

A panicked bird flying into a window or wall (often due to the detection of a predator) can induce concussive head trauma (Fig 39.41). Clinical signs include: a depressed bird sitting on the floor; neurological signs such as torticollis, opisthotonos, seizuring, paresis of a wing or leg; blood in the oral cavity, nares or ear canal; ophthalmologic lesions such as blindness, hemorrhage into the anterior or posterior chamber along with uveitis and possibly anisocoria; and sudden death. On necropsy, a hematoma on the skull can be observed. Treatment consists of: controlling swelling and inflammation with manitol; oxygen; controlling seizures (eg, with diazepam); providing supportive care, including adequate fluids (5% dextrose); and maintaining the bird in a cold, dark and quiet environment. Prognosis is guarded to poor, depending on the extent of cranial trauma.

Fig 39.41 | Trauma on the head of a bullfinch (*Pyrrhula* pyrrhula), due to its head impacting against the wire, is commonly seen with young birds in new cages.

Fig 39.42 | A rupture of the air sac is shown in this canary.

AIR SAC RUPTURE

Air sac rupture may be caused by trauma (bird flying into a window or wall) or chronic obstructive pulmonary disease. Clinical signs include swelling in the dorsolateral neck area due to rupture of the clavicular air sac (Fig 39.42). Treatment consists of puncturing the air sac swelling with a needle and addressing any primary disease. The likelihood of recurrence after puncturing is high.

Management of

Raptors

JAIME SAMOUR, MVZ, PhD, Dipl ECAMS

Fig 40.1 | Birds of prey have been used for hunting for thousands of years. This practice is believed to have started in Central Asia and its popularity soon spread across the Mogul and Ottoman empires.

The first manuscript in the Arab literature related to raptor medicine, "Benefits of Birds and the Comprehensive Treatment of their Diseases," was written by Adham bin Mahres Al Bahili during the reign of the 4th Caliph Haroon Al Rashid Al Abbasi (765 to 808 A.D.). This was a manuscript comprising 153 chapters in which issues such as diagnoses and diseases were first described. This manuscript was enriched by the participation of Al Hajaj bin Khaytamah during the reign of the 5th Caliph Mohammed Al Amin bin Haroon Al Rashid Al Abbasi (786 to 813 A.D.).

Sadly, there was a crucial hiatus in the continuing contribution of Arab literature to raptor medicine with the Mogul occupation of Baghdad in 1258 A.D. (Fig 40.1). Throughout the succeeding decades, falconry continued to decline in the domains of the Ottomans and Moguls. However, deep into the Arabian Peninsula, Bedouins continued the seasonal traditions of trapping, training and hunting with falcons as a means of supplementing their basic diet.

Falconry is still widely practiced in the Middle East, but is now considered a sport. The large population of falcons maintained annually in captivity prompted the creation of modern medical and research facilities in several countries in the region. These centers have contributed significantly in enhancing our knowledge of raptors during the past 25 years, particularly in falcon medicine (Fig 40.2). Similarly in North America and Europe, dwindling populations of peregrine falcons and bald eagles prompted the creation of rescue and rehabilitation centers and captive breeding programs.

Owing to the need to respond to medical and conservation trends, raptor medicine has become one of the fastest growing disciplines in avian medicine. This has

Fig 40.2 | The saker falcon (Falco cherrug) is the most popular species used in the sport of falconry in the Middle East. This species is the largest of the desert falcons. Arab falconers recognize several colors and color patterns for this species. Shown is a much-prized white saker falcon.

Fig 40.3 | The correct way to handle a large raptor is demonstrated on an immature white-tailed sea eagle (Haliaeetus albicilla). The towel placed around the body prevents damage to the feathers.

Fig 40.4 | Vultures have strong curved beaks capable of inflicting serious injuries during handling. Only trained personnel provided with suitable equipment (eg, leather gloves and aprons) should handle such birds.

Fig 40.5 | A typical free-flying molting room in the Middle East measures 15 x 8 x 5 m and is provided with red desert sand as a substrate. A single platform-type perch is placed around the room. Some birds have already been released, while others wait on stands until they are settled into the new environment.

been due to the dedication of individuals on both sides of the Atlantic and in the Middle East. This chapter is dedicated to these pioneers who, by their example, have inspired the author over the years.

Capture, Restraint and Transportation

Most raptors kept in captivity have strongly curved upper beaks and long, sharp, curved talons (the exception being vultures). Therefore, only well-trained personnel wearing adequate protective equipment (eg, leather gloves and aprons) should undertake handling and restraint of any of those species (Fig 40.3).

The techniques for capture and restraint vary with the circumstances (Fig 40.4). Birds kept free-flying in aviaries can be captured using nets fitted on long poles and later restrained by hand (Fig 40.5). Many birds are presented to veterinarians in transport crates. The position of the bird should be assessed before introducing the hands and arms into the crate. Make sure beforehand that the bird can easily fit through the door. Never introduce unprotected hands inside a crate holding a raptor. Trained raptors are easy to handle, since such birds are commonly hooded and can be captured on a gloved fist or a perch. The author favors capturing medium to small raptors by hand, then wrapping them with a soft towel to avoid damage to the feathers. Masking tape can be used to secure the towel around the body (Fig 40.6). Two operators should always be involved in the handling of large raptors (eg, vultures, eagles). Commonly, one oper-

Fig 40.6 | Two operators are involved when handling a saker falcon. One technician holds the leash with the gloved hand in case the procedure is aborted, and a second grasps the bird and casts it down on a soft cushion. The falcon is then wrapped with a thin towel to prevent feather damage.

Fig 40.7 | Weighing is an integral part of the medical management of raptors. A technician weighs a saker falcon using an electronic scale accurate to 1 g.

ator places one arm around the wings and holds the bird firmly against his/her body; the second hand holds the legs. While holding the legs, one finger should be placed between the tarsi to prevent lacerations to the skin around the joints. A second operator holds the bird's head and provides further assistance, if required.

Commercially available transport cages used for dogs and cats are suitable for transporting raptors. However, slight modifications such as placing burlap or canvas over grills and attaching pads to the roof of the cage, perches and/or carpet on the floor are all highly recommended measures. Trained hooded raptors usually travel well on perches when the cage is placed in the back of the vehicle or within the cabin of an airplane. During transport, it is highly recommended to protect the tail feathers with a tail guard made of lightweight cardboard or radiology film, fixed to the feathers with masking tape.

CLINICAL EXAMINATION

Clinical examination is similar to that performed on psittacines. The questions related to the clinical history of a bird or a flock can be grouped under three main headings: general clinical details, housing and feeding/watering (Tables 40.1-40.3).

Weighing

Raptors should be weighed upon presentation and regularly thereafter while under medical care. The body weight is a useful measurement in the assessment of health and disease and in monitoring the response to treatment. In addition, the weight of the bird is important for other purposes, such as sex determination, taxonomy or testimony in legal cases. Very often, a trained hooded raptor can be enticed to stand on a scale fitted with a perch. Commercially available electronic scales provided with perching surfaces are recommended (Fig 40.7).

*Modified⁷⁶

Conversely, birds can be placed on a scale while anesthetized or wrapped in a soft towel. Large birds such as eagles and vultures can be weighed together with the handler stepping onto a scale and the weight of the handler subsequently subtracted. The scales' accuracy should be +/- 1% of the body weight of the bird. With raptors used for falconry, the weight of falcon accessories (hood, jesses, bells) has to be taken into consideration. It is paramount importance that the bird be weighed with an empty crop.

PHYSICAL EXAMINATION

In common with other avian species, the physical examination of raptors involves handling and restraint. However, trained hooded raptors can be partially examined on the fist of the handler or while standing on a perch. It is important to carry out a significant part of the physical examination without handling and restraining the bird (Table 40.4). If the bird is a free-living or untrained individual, it will require restraint. Wrapping the bird with a soft towel is always very helpful in avoiding injuries to the main flight feathers. Extreme care should be exercised when examining a raptor. If the bird catches a handler with one or both feet during the handling process (commonly known as being "footed" or "taloned"), it is dangerous to attempt unlocking the grip. In most cases, the best solution is to release the bird. Subsequently, the bird can be recaptured within the room or aviary or recovered back to the glove if the bird is fitted with a leash and jesses.

Endurance Test

The endurance or stress test is very useful in assessing both the health and diseases of the respiratory system of captive raptors. This test can be carried out only on trained, small to medium-sized raptors, eg, hawks or falcons used in falconry. The respiratory rate is first obtained with the bird completely at rest and away from any noise or disturbance. As a general rule, the respiratory rate of a healthy raptor is 20 to 25 respirations per minute. Then, while on the glove, the bird is stressed by letting it vigorously flap its wings for 30 seconds. After this time, the bird is placed back on its perch and is allowed to rest for 2 minutes. The respiration is then assessed based on frequency and nature. After 2 minutes of complete rest, the respiratory rate is again obtained, which, in a healthy hawk or falcon, should be similar to the original prestress rate. Birds with lower respiratory system diseases would show deep, mostly abdominal respiration, with bobbing of the tail and body. The rate might be elevated to 80 to 120 respirations per minute. Radiology, endoscopy and hematology analyses are all highly recommended if a bird fails the endurance test. Examples of other causes of increased respiration fol-

Table 40.4 | Systematic Examination of Raptors

Anatomical Site	Examination
Eyes and eyelids	Symmetry, appearance, shape, discharge, wounds, swellings
Beak (upper/lower)	Appearance, grooves, cracks, splits, shape
Nares (nostrils)	Symmetry, shape, foreign material (eg, sand), discharge
Oropharynx	Color, swellings, caseous masses, blunted papillae, foreign bodies (eg, bones, tendons, string)
Ears	Symmetry, foreign bodies (eg, sand, ectoparasites), discharge
Neck/crop	Swellings, wounds, impaction
Body (chest and back)	Wounds, swellings, pectoral muscle mass, ectoparasites
Cloaca	Urate/feces seepage, swelling, masses
Wings	Symmetry, wounds, swellings, fractures, feather integrity
Tail	Swellings, feather integrity
Uropygial gland	Size, shape, quantity and consistency of oil
Legs	Symmetry, wounds, swellings, fractures
Feet	Symmetry, grip strength, skin condition, temperature, swellings, wounds, talon condition

lowing the endurance test include anemia, hyperthermia, septicemia, cardiac disease and ascites.

Clinical Laboratory Diagnosis

Clinical laboratory diagnosis is an essential component of raptor medicine. In this respect, veterinarians should be aware of the various assays available and be familiar with the protocols for the collection, submission and analyses of samples for the various assays (Table 40.5).

ADMINISTRATION OF MEDICATION

There is a wide choice of routes for the administration of medications to raptors. Each has its own advantages and disadvantages that should be taken into consideration before a particular route is selected (Table 40.6).

Bandages, Dressings and Casts

The placement of bandages, dressings and casts is part of the routine care of injured raptors or part of post-surgical protocols (Table 40.7).

The bandage most widely used among veterinarians working with raptors is a flexible self-adherent bandage^a that has revolutionized bandaging in veterinary medicine. It should be noted that this material and similar bandages will tighten when wet. Therefore, birds should be kept indoors, and access to open containers of water provided in the cages should be limited or monitored (Table 40.8). For further information on dressing and bandages of raptors, the reader is referred to a recent comprehensive publication.8

Foot castings are conforming devices commonly used in raptor medicine to prevent pressure-related trauma to a

Table 40.5 | Diagnostics

Table 1010 Diagnosits			
Discipline	Specimens	Assays	
Hematology	Blood samples for partial or complete hematology analyses	RBC, Hb, PCV, MCV, MCH, MCHC, WBC, differential white cell count, thrombocyte count and fibrinogen estimation	
Blood chemistry	Blood samples for partial or complete blood chemistry analyses	Glucose, total protein, albumin, globulin, A:G ratio, urea, uric acid, creatinine, bile acids, ALT (SGPT), ALP, GGT, AST (SGOT), CK, LDH, cholesterol, triglycerides, calcium, sodium, potassium, chloride, ionized Ca, Phos	
Parasitology	Biopsies, intestinal content, feathers, fecal samples, skin scrapping, swabs, tis- sue samples, worms (whole/section)	Direct wet smear, flotation, his- tology, staining with methylene blue stain, Lugol's iodine, rapid stains	
Bacteriology	Aspirates, air sac/tra- cheal/crop washing, biopsies, swabs, tis- sue samples	Aerobic and anaerobic cul- tures, antibiotic sensitivity test- ing, staining with Gram's stain and Ziehl-Neelsen stain	
Mycology	Aspirates, air sac/ tracheal/crop wash- ing, biopsies, impres- sion smears, swabs, tissue samples	Fungal culture, clarifying with potassium hydroxide, rapid stains, lactophenol cotton blue, India ink	
Serology	Blood samples	Antibody and antigen (eg, ELISA, IFA, PCR)	
Virology	Blood samples, tissues, swabs	Embryonated egg culture, cell culture, electron microscopy, PCR	
Cytology	Aspirates, impression smears, swabs	Staining with Gimenez stain, Papanicolaou stain, Macchia- vello stain, rapid stains	
Histopathology	Biopsies, tissue samples	Staining with hematoxylin and eosin stain, periodic acid-Schiff stain, PCR	

Table 40.7 | Use and Functions of Bandages

- 1. Avoid further damage (eg, self-inflicted lesions)
- 2. Prevent desiccation of tissue
- 3. Avoid contamination following surgical intervention
- 4. Holding dressings in place
- 5. Providing localized pressure to prevent hemorrhage following trauma or surgery
- 6. Prevent further trauma (eg, fractures)
- 7. Minimize pain post-surgery
- 8. Maintain intravenous or intraosseous fluid lines

Table 40.6 | Routes Commonly Used for the **Administration of Medications in Raptors**

Route of Administration	Site of Administration	Remarks	
Oral in water or food	Oropharynx, crop	Raptors do not always drink. It might be possible to hide medication in food.	
Oral gavage		Danger of aspiration of medica- tion. Tubes or cannulae with sharp ends should be avoided.	
Topical	Eyes, eyelids, ear, oropharynx, crop, skin	Excessive use of creams or oint- ments might cause matting of feathers; antiseptic solutions and sprays might stain feathers.	
Intramuscular	Pectoral muscles, quadriceps muscles	Main choice is pectoral muscles, avoid using long needles; irritant injections might cause muscle damage.	
Subcutaneous	Dorsal neck, crural area	When administering a large vol ume, distribute in different sites	
Intravenous	Jugular vein (right), basilic vein, saphe- nous vein	Avoid lacerating vein; ensure hemostasis post procedure.	
Intraosseous	Proximal tibiotar- sus, distal ulna	Placement of intraosseous cannula; efficient in debilitated birds.	
Intranasal	Nasal cavities	Avoid irritating substances.	
Intrasinal	Infraorbital sinuses	Avoid irritating substances; effective at treating sinusitis through flushing and direct injection.	
Intratracheal	Trachea, tracheo- bronchial syrinx, bronchi	Avoid irritating substances; avoid large volumes.	
Inhalation therapy (nebulization)	Upper respiratory system	Effective in the treatment of upper and lower respiratory disease; might lead to environmental contamination.	

Table 40.8 | Types of Dressings and Application

	• • • • • • • • • • • • • • • • • • • •
Туре	Application
Adhesive Dressing	s
Transparent dressings ^b	Thin film with a non-latex hypoallergenic adhesive. Allows vapor and oxygen exchange, protects from outside contamination.
Non-Adhesive Dre	ssings
Hydrocolloid dressing ^c	Adheres to skin but not to wound, creating a gelatinous mass over wound that provides a suitable environment for healing.
Moisture/vapor- permeable dressing ^d	Adequate maintenance of an aerobic environment under the dressing preventing scab formation and promoting epithelialization.
Low-adherent absorbent dressing ^e	Dry dressing with maximum absorbance ideal for infected suppurating wounds.
Petrolatum- impregnated fine mesh gauze ^f	Ideal for large areas of skin damage (eg, abrasion); prevents skin desiccation.

newly created wound in the postoperative treatment of pododermatitis or bumblefoot. Conversely, these can be used to prevent pressure sores to the opposite foot after fracture repair of a leg or to provide comfort during the non-surgical treatment of early bumblefoot lesions. Several materials and designs have been proposed over the years, ranging from a semi-rigid bridge made of thermoplastic tapeg under the foot, rigid shoes made of styrene plastic polymer,66 and form-fitting bandages

hardened with epoxy glue70 to a doughnut made of a ring heavily covered with soft bandaging (N.A. Forbes, personal communication). The author prefers to use a soft shoe made from 15- or 20-mm-thick rubber sheet, a material commonly used to make beach sandals. The form of the shoe is cut and shaped with a sharp blade. Round shapes to accommodate the toes and the ball of the foot are made using a red-hot rod. The shoe is fitted to the foot with a light conforming bandage.

Surgery

Many of the surgical procedures and ancillary techniques used in general avian medicine are applicable to raptors (Table 40.9). A short review of the different procedures and the different applications follows. There are other more specific surgical procedures pertinent to raptors and brief descriptions are provided.

KEEL INJURIES

Raptors in general, particularly those used in the sport of falconry, are prone to injuries of the carina, or prominence of the ventral median section of the keel, sustained when they crash on the ground during training exercises with lures or during fights with quarry. The most common type of injury is a longitudinal wound involving the skin and underlying tissue, but sometimes the lateral muscular mass is involved. If the injury is recent, closure should be attempted using conventional surgical techniques; if chronic, dry scabs and fibrous tissue should be debrided. In more severe cases with trauma or osteomyelitis of the carina, debridement of affected bone might be necessary to allow adequate closure.

CLAW DETACHMENT

Most raptors have long, curved talons integrated with a hard, highly keratinized casing covering the dorsal and lateral aspects, and a ventral, much softer plate. Very often, due to excessive length, deformities or trauma, claws can become detached, leading to extensive hemorrhage and exposure of the last phalanx. Intervention should be accomplished as soon as possible to maintain viability of the germinal tissue of the claw. The use of a hydrocolloid dressing^c and a conforming bandage is indicated. These should be changed every 5 to 7 days. Regrowth of the claw is possible, but this is a slow process sometimes requiring up to 2 to 3 months. Supplementation with 25 μ g/kg biotin POh is recommended during the regrowth period.

Distal Necrosis

This term is commonly used to describe necrosis of the terminal ends of the digits. The condition is often associated with extensive scabbing related to pox infection or frostbite. In the Middle East, there is a condition characterized by avascular necrosis of the distal end of the third digit (Fig 40.8). This is more often seen at the end of the hunting season and is very likely associated with cardiovascular changes as a result of a sudden cessation of exercise. A similar theory has been postulated for the development of bumblefoot in raptors. ^{26,29} Distal necrosis invariably leads to amputation of the digit (Fig 40.9).

Table 40.9 | General Surgical Procedures and Indications in Raptors

Surgery	Indication
Sinusotomy	Removal of trichomoniasis granulomas, draining and flushing in severe obstructive bacterial or fungal sinusitis
Ingluviotomy	Removal of foreign bodies and trichomoniasis granulomas, removal of ingested food in sour crop
Tracheotomy	Removal of aspergillomas and trichomoniasis granulomas from tracheal lumen and syrinx
Celiotomy	Removal of aspergillomas pre- or post- medical treatment
Proventriculotomy Ventriculotomy	Removal of foreign bodies, impaction
Salpingohysterectomy	Removal of uterus and oviduct, sterilization of females
Orchidectomy	Removal of testes, sterilization of males
Vasectomy	Sterilization of males (libido intact)
Cloacopexy	Correction of cloacal prolapse

Table 40.10 | Common Endoscopy Applications in Raptor Medicine*

Application	Anatomical Site
Otoscopy	External auditory canal
Rhinoscopy	Nasal cavities
Pharyngoscopy	Oropharynx
Tracheoscopy	Trachea/tracheobronchial syrinx/bronchi
Ingluvioscopy	Crop
Esophagoscopy	Esophagus
Gastroscopy	Proventriculus, ventriculus
Celoscopy	Coelomic cavity
Cloacoscopy	Cloaca

^{*}Modified⁷⁷

Ring Constriction

This is a condition characterized by an annular or circumferential constriction at a particular area of the toes. The etiology in many cases remains unclear. In the Middle East, ring constriction is very often observed around the hallux or first toe of hunting falcons caused by entanglement with the thin, rope-like jesses used in Middle Eastern falconry (Fig 40.10). Treatment of ring constriction entails the removal of the annular scab and attempted closure with conventional suturing techniques. If suturing is not possible due to a large gap between the wound edges, hydrocolloid dressings^c, together with a conforming bandage changed at regular intervals, is used to achieve healing by granulation and epithelialization (Fig 40.11) (see Chapter 35, Surgical Resolution of Soft Tissue Disorders).

ENDOSCOPY

Endoscopy (*Greek: endon = within, skopein = to examine*) is an essential medical procedure used routinely in raptor medicine as an ancillary technique in the diagnosis of certain medical conditions (eg, aspergillosis, candidiasis) (Fig 40.12), assisting in the collection of

Fig 40.8 | Distal necrosis is a poorly understood condition in raptors. In falcons, the middle digit is most often affected. The etiology might involve vascular disorders originating from a sudden cessation of activity.

Fig 40.10 | Arab falconers use jesses fitted with a thin cotton or nylon string. This string very often becomes entangled around the hallux or first digit, leading to ring constriction.

Fig 40.12 | Rigid endoscopes are normally used to examine the upper digestive tract of raptors under anesthesia. Candidiasis and esophageal trichomoniasis are two of the diseases diagnosed with the aid of endoscopy.

Fig 40.9 | Peregrine falcon (Falco peregrinus) with a severe self-inflicted injury in the middle digit. This is a common occurrence in newly wild-caught individuals of this species. The damage was extensive, necessitating complete amputation of the digit.

Fig 40.11 | Severe ring constriction around the hallux. Satisfactory resolution can be achieved by periodic application of hydrocolloid dressings to the affected area. More severe cases may require surgical reconstruction.

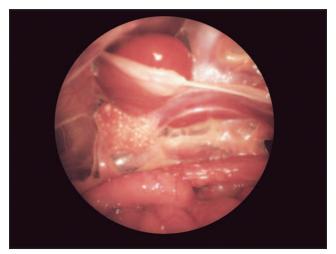

Fig 40.13 | Endoscopic view of the reproductive tract of an immature bird. Endoscopy offers the opportunity to examine the organs directly for signs of health and disease and to collect biopsies.

Fig 40.14 | Fracture of the tibiotarsal bone in a saker falcon. This is the most common type of fracture encountered in clinical practice with captive raptors. Fractures of this bone tend to occur in newly tethered birds and during training exercises.

Fig 40.15 | The bird in Fig 40.14. The fracture was repaired using a shuttle pin and a type II external skeletal fixator. Two acrylic bars and additional metals pins within the tubing were used to maintain the fixator in position and provide extra strength.

Fig 40.16 | A similar fracture of the tibiotarsus in a gyr-peregrine hybrid falcon. This fracture was repaired using an intramedullary pin inserted in a normograde fashion from the tibial crest, a positive profile threaded pin placed distally and tie-in using a bar and clamps.

Fig 40.17 | The falcon in Fig 40.16. Note the bandage covering the external skeletal fixator and the shoe placed on the opposite foot to prevent bumblefoot. In uncomplicated cases, full healing should be expected in 4 to 6 weeks.

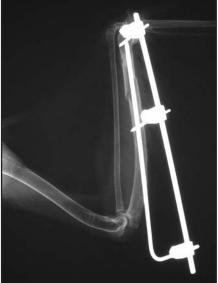

Fig 40.18 | Oblique fracture of the distal ulna repaired using an intramedullary pin inserted in normograde fashion from the proximal ulna, two positive profile threaded pins placed in the proximal and distal fragments, and tie-in using a bar and clamps.

Fig 40.19 | Fracture of the first phalanx of digit 2 in a saker falcon. There was extensive soft tissue swelling and lysis of the bone fragments requiring amputation of the digit.

biopsies (eg, liver biopsy) and assisting in the performance of some intracoelomic surgical interventions (eg, vasectomy) (Fig 40.13, Table 40.10) (see Chapter 24, Diagnostic Value of Endoscopy and Biopsy).

ORTHOPEDIC SURGERY

Raptors are very often presented to rescue and rehabili-

tation centers with luxations and fractures⁶² caused by inadequate management, trapping, injuries by larger migratory raptors and collision with moving vehicles or stationary objects (eg, fences, towers, utility poles) (Figs 40.14-40.17). The goal of return to flight and the associated need for retention of soft tissue and joint integrity make orthopedics in raptors destined for either

Fig 40.20 | Lateral radiograph of a falcon showing extensive osteoarthritic changes of the vertebral synsacral joint. The only clinical sign was the inability to maintain a straight position while standing. Damage tends to occur due to collision-type injuries.

falconry or release a different proposition than it is for pet psittacines. Table 40.11 summarizes orthopedic techniques used in raptor medicine (Table 40.11, Figs 40.15-40.20). For further information, the reader is referred to published information. ^{25,62,64,72} (See Chapter 34, Surgical Resolution of Orthopedic Disorders).

Pododermatitis

Pododermatitis or bumblefoot is a common medical condition of captive raptors and is characterized by inflammation and often abscessation of the sole of the foot or the plantar aspect of the digits. This condition appears to be caused by a combination of factors including poor nutrition, obesity, inadequate perches, lack of exercise, poor blood circulation to the foot and cardiovascular changes at the end of the hunting season^{26,29} (Figs 40.21, 40.22). Some raptor species appear to be more susceptible to this condition than others. For instance, the incidence of bumblefoot appears to be higher in falcons but

Fig 40.21 | Plantar view of the foot of a saker falcon showing a large area of dry skin in the center of the sole. The adjacent papillae are flattened, having lost the form and texture due to the use of inadequate perches and lack of exercise.

Table 40.11 | Techniques for Fracture Repair in Raptors 62

Idble 40.11	echniques for Fracture Repair in Raptors ⁹²
Anatomical Site	Technique
Coracoid	Conservative treatment (eg, immobilization of the wing).
Humerus Proximal	Tension band technique. Two Kirschner wires driven normograde cross-pin fashion, tension band formed by cerclage wire.
Mid-shaft	Intramedullary pin type I external skeletal fixator tie- in technique. Steinmann intramedullary pin normo- grade fashion driven from the distal end of the humerus. Placement of two positive profile threaded pins, one in the dorsal condyle, and the second placed close to the curvature of the pectoral crest. Tie-in with a fixator bar and clamps ¹ , thermoplastic tape ⁹ or acrylic bar ^k .
Distal	Intramedullary pin type I external skeletal fixator tie- in technique. Two Kirschner wires driven normograde cross-pin fashion, placement of a positive profile threaded pin¹, on the curvature of the pectoral crest. Tie-in with a fixator bar and clamps¹, thermoplastic tape³ or acrylic bar².
Radius and Ulna	"Figure eight" coaptation bandage. Intramedullary pin type I external skeletal fixator tie-in technique. Normograde placement of Steinmann intramedullary pin, normograde fashion driven from the proximal end of the ulna and Steinmann intramedullary pin normograde or retrograde fashion in the radius, placement of two or more positive profile threaded pins tie-in with a fixator bar and clamps, thermoplastic tape ⁹ or acrylic bar*.
Major Metacarpal	Coaptation with splint or thermoplastic tape splints. Intramedullary pin type I external skeletal fixator tie-in technique. Steinmann intramedullary pin or Kirschner wire in normograde or retrograde fashion, placement of two or more positive profile threaded pins tie-in with thermoplastic tape or acrylic bar.
Femur Proximal	Tension band technique. Two Kirschner wires driven normograde cross-pin fashion, tension band formed by cerclage wire.
Mid-shaft	Intramedullary pin type I external skeletal fixator tie- in technique. Steinmann intramedullary pin retro- grade fashion, placement of two or more positive profile threaded pins tie-in with a fixator bar and clamps, thermoplastic tape® or acrylic bar*.
Distal	Two Kirschner wires driven normograde cross-pin fashion, placement of a positive profile threaded pin on proximal femur. Tie-in with a fixator bar and clamps, thermoplastic tape ⁹ or acrylic bar ^k .
Tibiotarsus	Intramedullary pin type I external skeleton fixator tie-in technique. Steinmann intramedullary pin normograde fashion driven from the tibial crest, placement of a positive profile threaded pin distally tie-in with a fixator bar and clamps, thermoplastic tape ⁹ or acrylic bar ^k .
Tarsometatarsus	Type II external skeletal fixator. Placement of four pins, tie-in with fixator bar and clamps, thermoplastic tape ⁹ or acrylic bar ^k .

Fig 40.22 | The foot in Fig 40.21. The dry skin was removed by brushing gently, exposing underneath an early ulcerative lesion in the skin. This is, in the author's opinion, the most common presentation of bumblefoot in captive raptors.

Fig 40.23 | Severe bilateral bumblefoot in a saker falcon, with soft tissue swelling and underlying infection. Such cases are not amenable to treatment due to large skin deficits that remain after scab removal. The use of skin flaps has been attempted with little success.

seldom occurs in hawks.26 In most cases, the preferred therapy involves the surgical removal of scabs and adjacent necrotic and purulent tissue, followed by suturing to achieve healing by first intention (Fig 40.23). The placement of antibiotic-impregnated polymethylmethacrylate beads within the newly created cavity improves the rate of healing.⁶⁹ If the skin deficit is relatively large and complete closure is not possible, partial closure might be attempted with a purse-string suture together with hydrocolloid dressings^c to promote healing by second intention. The use of foot casting together with conforming bandages as part of the postoperative treatment is highly recommended (see previous section on foot casting) (Fig 40.24).

IMPING

Imping, a medieval falconry term, is the art of repairing fractured or bent feathers. The integrity of the primary and tail feathers is of the utmost importance for flight and performance in raptors destined for release back into the wild or for those used in the sport of falconry. Feathers tend to suffer severe bends or fractures during captivity in rescue and rehabilitation centers (poor aviary or holding cage design), training or hunting (crash landings or fighting with quarry) or because of inadequate handling and transport (no tail guard). Imping is usually carried out by total or partial feather replacement or by external splinting^{45,78,89} (Fig 40.25). See Table 40.12 for a list of materials used for imping.

For a total and partial feather replacement, it is necessary to procure a feather that is of the same species, side (eg, wing feather), size, sex, age and color. Rescue and rehabilitation centers and medical facilities concerned with raptors usually maintain a collection of molted feathers and feathers obtained from carcasses. It is rec-

Fig 40.24 | A custom-made protective shoe made from a soft rubberized material. These are used to protect surgical sites in the sole of the foot and to prevent pressure sores on the opposite foot after orthopedic surgery.

Fig 40.25 | Materials and equipment required for feather repair and total or partial feather replacement.

Table 40.12 | Materials and Instruments for Imping

- · Scissors, small, sharp, fine-pointed
- Nail cutter, medium and large (eg, cat and dog size)
- · Imping needles, made from steel hairpins, long 50 mm x 1.5 mm, medium 40 mm x 1.5 mm, short 30 mm x 1.5 mm, fine 25 mm x 1 mm
- Hair clips (aluminum) 100 mm long
- · Nail file, fine
- · Methacrylate glue
- · Epoxy glue, fast setting
- · Baking soda, finely powdered
- · Pliers, curved, fine-tipped
- Bamboo pegs, different diameters (barbecue skewers are ideal)
- · Knife, interchangeable blades
- Cardboard cards, thin, 5 cm x 5 cm square

ommended to carry out feather examination and feather repair procedures under general inhalant anesthesia.

Total Feather Replacement

Total feather replacement is indicated when the feather is fractured at the proximal section of the feather shaft. After examination and determining the number of feathers for

Fig 40.26 | This falcon sustained a fracture of a tail feather with complete loss of the fragment. The fracture occurred in the first third of the shaft, requiring full feather replacement.

Fig 40.28 | Tail of the falcon in Figs 40.26 and 40.27, showing the new feather in place. In addition, the two deck or central feathers were repaired using the partial replacement technique.

Fig 40.27 | A similar feather was procured and cut to the same size as compared with the feather on the opposite side of the tail. A pre-made short bamboo peg was placed between the two fragments and glued into position using rapid-setting epoxy glue.

Fig 40.29 | This saker falcon has suffered fractures of primaries 1st, 2nd and 3rd (8th, 9th and 10th according to the Western ornithology) with loss of feather fragments. Partial feather replacement is indicated in this particular case.

repair, the area should be prepared. First, the covert feathers are deflected backward and held in place with masking tape to expose the base of the shaft. The fractured feather is cut approximately 15 to 25 mm from the skin with a nail cutter (Fig 40.26). The new feather is placed in position to assess the length, making sure to maintain bilateral symmetry with the opposite wing when replacing a wing feather, or the opposite side if replacing a tail feather. If the feather from the opposite side is missing, the veterinarian or technician should follow the feathering pattern of the wing or tail characteristic of the species (eg, in a peregrine falcon, primary 10 [No 1 in Arab falconry] is approximately 5 to 8 mm shorter than primary 9 [No 2 in Arab falconry]). This general ornithological knowledge is essential to carrying out feather replacement adequately. The feather is cut, and a bamboo peg about 80 to 100 mm long is prepared by sharpening

both ends to approximate the diameter of the shaft of the new feather and the empty shaft of the wing. The wooden peg is first glued into the shaft of the new feather with fast-setting epoxy. Additional glue is then placed (eg, injected with a 1-ml tuberculin syringe) into the shaft, making sure the feather is properly aligned. A small piece of cardboard should be placed under the imping site to prevent the glue from smearing onto adjacent feathers (Fig 40.27). The wing or the tail should then be closed in the natural anatomical position and all the feathers held in place with hair clips until the glue is set (Fig 40.28).

Partial Feather Replacement

Partial feather replacement is indicated if the fracture has occurred at the mid-shaft or at the distal end of the feather. If a fracture is complete and the feather fragment

Fig 40.30 | Feather fragments from the same species, size, side (eg, left wing), sex, age and color have to be procured. Imping needles of a suitable size are used to join the fragments. The needle is first fixed into the distal fragment using methacrylate glue. The fragment is then pre-placed into the fractured fragment to check alignment before gluing into position.

Fig 40.32 | A severe bend in the mid shaft of a main flight feather. Note that the integrity of the feather shaft has been maintained

Fig 40.31 | The falcon in Fig 40.30 with the three feathers repaired. It is highly recommended to place an external splint as that described in Figs 40.32 and 40.33 to reinforce the ventral aspect of the imping surface. The dorsal aspect can be filed to produce a smooth surface and then colored using a brown

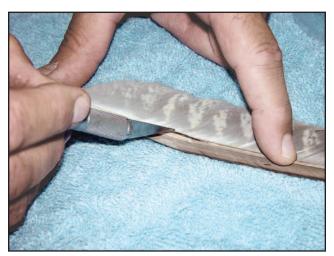

Fig 40.33 | The preliminary stage of the technique used by the author for feather repair involves splitting the ventral aspect of the shaft, 12 to 15 mm in either direction from the bend, using a sharp knife.

is missing, a similar fragment must be procured from a donor feather (Fig 40.29). Conversely, the fragment might then be reattached. In both cases, the ends of the fragments are smoothed out with a fine-pointed scissor and a fine nail file. A previously prepared imping needle of suitable length and diameter is carefully inserted in both fragments to make a narrow channel. The needle is then fixed onto the fragment with a small amount of methacrylate glue. The fragment is attached onto the rest of the feather and checked for correct alignment. Additional glue is then applied onto the free end of the needle of the fragment, which is then attached to the rest of the feather (Fig 40.30). Pressure should be applied over the imping site with fine-tipped, curved hemostats or pliers for approximately 30 seconds to allow the glue to set. The dorsal and ventral aspects of the fracture line

are then filed with a fine nail file. In partial replacement, it is strongly recommended to apply a ventral external splint in addition to the method described above to produce a more satisfactory and efficient result. The dorsal aspect of the imping site can be colored, if necessary, with a marker pen (Fig 40.31).

Bent Feather Repair

Moderate or severe bending might occur at different levels of the shaft. Bends are repaired using the external splinting technique. The bend is straightened on its dorsoventral axis with a pair of fine-tipped, curved hemostats or pliers (Fig 40.32). The ventral aspect of the feather shaft is then split 12 to 15 mm in either direction from the bend (Fig 40.33). A suitable imping needle is placed in the newly created groove and secured firmly

Fig 40.34 | The second stage of this technique involves the placement of an imping needle within the newly created groove. Methacrylate glue is then used to secure the needle into position.

Fig 40.36 | After completing the splint, fine-grain nail files are used to smooth the newly created surface. The final product blends very well with the shaft of the feather, resulting in a satisfactory cosmetic repair.

with methacrylate glue (Fig 40.34). The ventral surface of the feather shaft around the bend is roughened with a fine nail file. A thin layer of methacrylate glue is smeared onto the site approximately 10 mm to either side of the bend. A small amount of baking soda is sprinkled directly onto the freshly glued surface (Fig 40.35). The sodium bicarbonate binds with the glue creating a strong cement-like layer over the bend. The procedure can be repeated two or three times to create a thicker layer if this proves necessary. The upper surface and the edges of the newly created layer are filed with a fine nail file (Fig 40.36). The external splint is translucent, making the need for coloring unnecessary.

COPING

Coping is a medieval term meaning the trimming and reshaping of talons and beak. Overgrown talons and

Fig 40.35 | The final stage of feather repair involves the creation of an external splint using a combination of methacrylate glue and sodium bicarbonate to produce a cement-like layer over the original bend.

Table 40.13 | Materials and Instrumentation for Coping

- · Nail cutter, guillotine-type
- Nail cutter, large, human-type
- · Nail file, fine
- Methacrylate glue
- · Baking soda, finely powdered
- · Knife, interchangeable blades
- · Silver nitrate pencil

beaks are commonly found in captive raptors due to the insufficient wear associated with the use of soft, inadequate perching surfaces and lack of a natural diet. More severe cases indicate malnutrition. See Table 40.13 for a list of materials used for coping.

Talons

Knowledge of the size and morphology of the talons of different raptor species is essential. Overgrown talons are best trimmed with a guillotine-type nail cutter. The talon is then reshaped with a sharp blade and nail files. Excessive trimming would invariably lead to hemorrhage. The use of a thermocautery or a silver nitrate pencil is usually sufficient to arrest any hemorrhage. The use of a lanolin or paraffin-based hand cream is recommended after trimming and reshaping of the talons. Raptors used in the sport of falconry should have the talons trimmed before placing them into molting chambers (Fig 40.37).

Beak

In raptors, the shape of the beak is species-specific. For instance, Buteo spp. and Accipiter spp. possess a hooked beak design for tearing at prey, while the beak of Falco spp. has a tomial tooth used presumably to sever the head of prey. Knowledge of the normal

Fig 40.37 | Overgrown and deformed talons are the result of the use of inadequate perching surfaces. The talons of the hallux are more susceptible to deformities if birds are confined to small round perches such as the Arab-style stand.

Fig 40.39 | Severe bilateral splitting of the upper beak with lateral deviation of the lower beak in a peregrine falcon due to neglect. The coping of such a condition requires several sessions over several months to fully correct the different defects.

Fig 40.38 | Saker falcon with a long deformed beak after the molting season. Coping, an old medieval term, is the art of trimming and reshaping of the beak and talons of raptors. Coping of the beak is usually carried out using nail cutters and fine-grain nail files.

Fig 40.40 | Deep unilateral groove in the beak of a saker falcon. This condition commonly originates from scratch injuries sustained at the anterior aspect of the nares, damaging the germinative tissue of the beak and leading to a growth disorder.

morphology of beaks in raptors is essential before undertaking any reshaping.

An overgrown beak is simply trimmed back with humantype nail cutters, and the tip reshaped with nail files or a rotary grinding tool (Fig 40.38). The lateral aspect of the beak of captive raptors is prone to cracks and fissures, which can be prevented by providing hard surfaces (stones) where the bird can both clean its beak and file it regularly to maintain its shape. Cracks and fissures should be trimmed as soon as possible to prevent more serious conditions such as fractures (Fig 40.39). Lateral grooves on one or both sides of the beak are found commonly in raptors, but particularly in falcons (Fig 40.40). It has been suggested that these grooves in falcon beaks are due simply to old age. An alternate explanation, adhered to by this author, involves the grooming practices of falcons. During routine grooming, falcons tend to scratch the head with their talons. Puncture wounds to the eyes or

scratches to the eyelids and the nares are often observed. During scratching, a falcon can easily hook a talon on the anterior aspect of the nares causing a laceration. This wound is created on the edge of the germinative tissue of the beak, creating a groove as the beak grows. Very little can be done to correct this condition. Temporary filling of the defect with methacrylate glue and baking soda or commercially available beak repair kits has been successful. However, as the beak grows, continuous repairs will be required every 8 to 12 weeks.

HOSPITAL CARE

In order to be treated for selected medical conditions, raptors must be hospitalized (Fig 40.41). Free-living raptors usually tolerate small cages, provided these are fitted with curtains and maintained in quiet, semi-dark rooms. Falconry birds can be kept unhooded on wall or floor perches. Hoods are commonly used only during

Fig 40.41 | Large raptors can be kept in small, secluded aviaries during hospitalization. This griffon vulture (Gyps fulvus) was admitted for the treatment of a compound fracture involving the humerus.

routine cleaning and for handling purposes. Hospitalized raptors should be fitted with a tail guard as described in the earlier section on capture and restraint.

Handling of raptors for medication administration and cleaning should be kept to a minimum; non-intrusive cages with a tray fitted below a slatted floor are ideal. Furthermore, a significant amount of medications can be administered hidden in food (eg, tablets or powdered medication inside the heart of a quail). There are cases, however, in which medication has to be administered by injection, nebulization or topically, and handling is therefore necessary. Hooded raptors are easier to maintain under hospital conditions. Changeable substrate (eg, carpeting, sand, newspaper) under floor or wall perches allows easy maintenance of such birds. The administration of medicaments to such birds also is facilitated, since hooded raptors can, for instance, be given intramuscular injections in the chest musculature by a single operator without restraint.

DIET AND FEEDING STRATEGY

Hospitalized raptors can be fed a variety of food items such as feathered and unfeathered quail, mice, rats, ducklings, rabbits, day-old chicks and fish for species such as ospreys (Pandion baliaetus) and bald eagles (Haliaeetus leucocephalus). Thiamine supplementation at a rate of 2 mg/kg PO weekly is indicated when using frozen-thawed fish. The daily provision of casting material in the form of fur and feathers is of the utmost importance. Casting material should be offered only to raptors in which the gastrointestinal tract is working normally. However, raptors very often refuse to eat, and it might prove necessary to force-feed them in order to meet their daily nutritional requirements. For a list of

Table 40.14 | Force-feeding Materials

- Stomach tube, blunt end, plastic (5 mm, 8 mm or 12 mm in diameter)
- Feeding syringe, 60 ml
- Lubricantⁱ
- · Formula container

Table 40.15 | Force-feeding Formula^e

Formulae	Ingredients	Instructions	
Formula 1 - Induction	Add 15 ml water to 20 g ground whole unfeathered quail +10 g ground beef or chicken liver + ½ teaspoon glucose-electrolyte prepara- tion in powder form.	Administer 20 to 30 ml of mix per kg body weight, 3 or 4 times daily during first day of admission.	
Formula 2 - Intensive	Add 20 g of ground whole unfeathered quail +10 g ground beef or chicken liver +1 whole egg + ½ teaspoon glucose-electrolyte preparation in powder form.	Administer 30 to 40 ml of mix per kg body weight, 3 or 4 times daily; weigh daily, until the desired body weight is reached.	
Formula 3 - Maintenance	Add 5 ml water to 20 g of unfeathered ground quail + 10 g ground beef liver + ½ teaspoon glucose-electrolyte preparation in powder form.	Administer 30 to 40 ml of mix per kg body weight, 3 or 4 times daily; weigh daily.	

materials used to force-feed raptors, see Table 40.14. For a complete description of dietary management of captive raptors, the reader is referred to comprehensive previously published accounts.3,61

Force-feeding is the introduction of nutritional formula into the alimentary tract by means of a stomach tube, and injected using a large syringe. There are several commercially available diets that can be used. However, the author favors the force-feeding diets and feeding strategy for raptors shown in Table 40.15. In fish-eating species, fish can be incorporated into the diet by substituting it for the quail, beef or chicken.

To force-feed a raptor, the thoroughly lubricated feeding tube is passed gently into the back of the oropharynx, through the crop and then into the esophagus toward the right side of the neck. Great caution should be exercised while manipulating the tube within the crop to avoid folding the tube or causing a penetrating wound through the crop wall. During force-feeding, the neck of the bird should remain extended to discourage regurgitation. Feeding tubes and syringes must be thoroughly washed, disinfected and rinsed (1 ml quaternary ammonium and biguanadine compounds disinfectantⁿ in 500 ml water for 2 to 5 minutes) prior to using them on another patient.

BIOSECURITY

Biosecurity is defined as a series of measures undertaken within a building or building complex to prevent the propagation and spread of diseases. Housing a large

Fig 40.42 | Disinfection is the backbone of any biosecurity program. The technician is using a fogging unit loaded with a solution of commercially available disinfectantⁿ within a falcon room. Note that the procedure is being carried out in the presence of the birds.

number of raptors (eg, captive breeding program) within the same facility represents a potential risk if basic biosecurity rules are not followed. The risk becomes more significant when there is a constant flow of raptors from different origins such as hospitals or rescue and rehabilitation centers. For instance, an epornitic outbreak of pox within a facility housing 15 different species of raptors was reported in the USA. The author has observed similar outbreaks of pox and Newcastle disease in falcon molting and breeding facilities in the Middle East. In some cases, outbreaks of Newcastle disease were traced to the consumption of infected quail and pigeons. In other instances, pox and Newcastle disease were traced to affected falcons placed in close contact with healthy birds without having gone through a quarantine period.

One of the main pillars of any biosecurity program is disinfection. Disinfection is defined as a procedure intended to eliminate from a particular defined area any pathogenic organism or to render them inert with one or a combination of chemicals. There are many products available on the market that could be used within a biosecurity program. Such products should be non-toxic, non-irritating, non-corrosive and, ideally, biodegradable. Once a suitable product has been obtained, the next step is to design and implement a disinfection program for the facility (Fig 40.42).

The disinfection program followed at the Fahad bin Sultan Falcon Center facilities in Riyadh, Kingdom of Saudi Arabia (Table 40.16) is based on the use of a recently introduced quaternary ammonium and biguanadine compounds disinfectantⁿ.

Infectious Diseases

Infectious diseases are those disorders produced by the invasion and propagation of microorganisms in body tissues. Infectious diseases may produce no clinical signs, or they may cause a myriad of reactions, including localized cellular injury due to competitive metabolism, toxins, intracellular replication or antigen-antibody response. Infectious diseases can be divided into four main groups: Parasitic, bacterial, viral and fungal diseases.

PARASITIC DISEASES

Parasites (*Greek: Parasitos*) are organisms that live upon or within other living organisms, at the hosts' expense. Parasites are often found associated with free-living and captive raptors. The relationship between the parasite and its host does not necessarily translate into overt disease. However, both intrinsic (eg, severe weight loss, immunosuppression, toxicosis, collateral infectious disease) and extrinsic (eg, heat stress) factors can exacerbate the effect of parasites, resulting in adverse clinical signs.

In general, parasites can be classified as ectoparasites (*Greek: ecto = outside*) and endoparasites (*Greek: endon = inside*). However, in the context of this chapter, the main parasites of raptors will be described under the grouping macroparasites (arthropods, helminths) and microparasites (protozoa, hematozoa).

Macroparasites

Arthropods

Arthropods or ectoparasites are invertebrates commonly found associated with the integument of free-living and captive raptors. ^{29,42,92} All ectoparasites of raptors are classified under the phylum Arthropoda, classes Insecta and Arachnida, and include mainly ticks and mites (Acarina), fleas (Siphonaptera), larvae of flies and louse flies or hippoboscids (Diptera) and chewing lice (Phthiraptera, formerly Mallophaga). ⁴² Some species of ectoparasites (eg, lice, mites) live permanently on the host while others (eg, ticks, flies) only temporarily (Table 40.17).

For more information on geographical distribution, pathogenesis and suggested control of ectoparasites in raptors, the reader is referred to excellent reviews recently published. 42,92,109

The treatment used by the author for the control of ectoparasites in raptors is an insecticide containing 1.25 g/L permethrin, 6.25 g/L piperonyl butoxide and 20 mg/L methoprene°. This is sprayed lightly under the wings, over the neck and back, and under the tail. Meticulous cleaning and spraying of the rooms, cages or aviary might be required.

Table 40.17 | Common Ectoparasites Found in Raptors

	· · · · · · · · · · · · · · · · · · ·		
Hard ticks	lxodes ricinus, I. arboricola, Hyalomma marginatum, H. rufipes, Rhipicephalus turanicum, Amblyomma lepidum

Mites	Dermanyssus gallinae, Ornithonyssus sylviarum, Knemidokoptes mutans, Kurodaia haliaeeti, Bonnetella fusca, Boydaia falconis		
Fleas	Echidnophaga gallinacea, Ceratophyllus gallinae		
Larvae of flies	Lucilia spp., Calliphora spp., Prosimulium spp., Carnus hemapterus, Passeromyia heterochaeta		
Louse flies	Ornithomya avicularia, Pseudolynchia canariensis, Icosta Americana, Ornithomya anchineuria		
Lice	Craspedorrhynchus spp., Aegypoecus spp., Laemobothrion tinnunculi, Degeeriella rufa, D. discocephala stelleri, Falcolipeurus spp. Kelerinirmus rufus camtschaticus, Caracaricola chimangophilus, Pterophilus sudanensis, Colpocephalum zerafae		

Fig 40.43 | Large number of *Serratospiculum seurati* filarial worms within the coelomic cavity of a saker falcon. Falcons often carry a heavy parasitic burden without displaying any clinical signs. However, the falcon depicted in this photograph had severe air sacculitis and associated dyspnea.

Helminths

Helminths (*Greek: Helmins = worm*) are a group of parasitic worms with various structural and behavioral characteristics that inhabit different organ systems of raptors. These can be classified under the following groups: trematodes (flukes), cestodes (tapeworms), nematodes (roundworms) and acanthocephalans (spiny-headed worms).⁴⁴

It is generally believed that large numbers of certain parasites can coexist within the host without posing any serious health threat. For instance, exceedingly large numbers of *Serratospiculum seurati* filarial worms have been observed within the coelomic cavities of recently caught free-living saker falcons upon routine endoscopy in the Middle East*5 (Fig 40.43). The endoscopic examinations were carried out as an integral part of health assessments. In most cases, finding such heavy parasitic burdens was incidental and did not correlate with any obvious clinical signs. However, in severe infections, *S. seurati* has been found associated with pneumonia, air sacculitis and early lesions of aspergillosis.*5

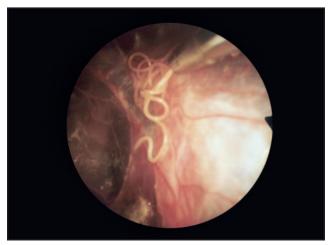

Fig 40.44 | It is a common and widespread practice to manually remove Serratospiculum seurati filarial worms from the coelomic cavity following ivermectin treatment. This is unnecessary in most cases as the worms are commonly absorbed. The current treatment of choice for serratospiculiasis is 1 mg/kg PO q7d x 2 weeks of moxidectin.

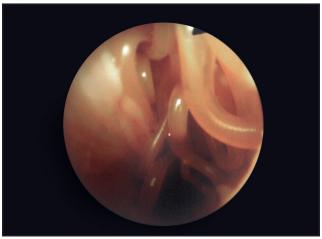

Fig 40.45 | Adult Physaloptera alata worms attached to the esophagus of a lanner falcon (Falco biarmicus). This was an incidental finding during a routine endoscopy examination of the upper digestive tract. The ova of this species are very similar to those of Serratospiculum seurati, but differ slightly in size and shape.

It is a good practice to screen captive birds for parasites a minimum of two times a year. This should be part of a much wider preventive medicine program. When possible in captive breeding projects, up to three fecal samples should be collected at intervals of 24 to 48 hours to provide a better qualitative and quantitative assessment of the presence of parasites. It is imperative to educate raptor owners and keepers to the fact that the treatment of parasites involves more than administering pharmacological compounds. Other important aspects of parasitic control include strict hygiene measures and modifications to aviaries and enclosures to prevent access to intermediate hosts (eg, placement of pebbles as substrate in open aviaries to prevent raptor's access to earthworms).

The following table (Table 40.18) provides a list of the most common endoparasites of raptors. For further information on the taxonomy and distribution of endoparasites in raptors, the reader is referred to a com-

Table 40.18 | Common Endoparasites Found in Raptors

· · · · · · · · · · · · · · · · · · ·

Nematodes	Baruscapillaria falconis, Capillaria tenuissima, C. falconis, C. contorta, C. strigis, Cyathostoma americana, C. brodskii, C. lari, Diplotrianea falconis, Eucoleus dispar, Porrocaecum angusticolle, P. depressum, Serratospiculum seurati, S. tendo, Serratospiculoides amaculata, Syngamus trachea, Synhimantus laticeps, S. hamata, Physaloptera alata, Procyrnea leptoptera, P. mansioni, Tetrameres accipiter
Acanthocephalan	Centrorhynchus aluconis, C. buteonis, C. globocaudatus, C. kuntzi, C. olssoni, C. robustus, C. spinosus, C. tenuicaudatus, Mediorhynchus armenicus, M. papillosus

prehensive and excellent review recently published.44

Treatment

Praziquantel is widely used for the treatment of trematodes and cestodes at the dose rate of 50 mg/kg PO or SC as a single dose.97 Alternatively, niclosamide at the dose rate of 125 mg/kg PO also as a single dose has been used for the treatment of cestodes. The author, however, currently is successfully using a compound mixture, providing a total of 10 mg/kg PO praziquantel, for the control of trematodes and cestodes in falcons, administered in two doses 1 week apart. In addition, this compound provides 10 mg/kg oxfendazole. The pharmacological action of oxfendazole on nematodes in raptors has not been ascertained. Fenbendazole, at the dose rate of 25 mg/kg PO for 3 to 5 consecutive days, is used very commonly for the treatment of nematodes in raptors. 29,47,96 Levamisole has been recommended for the treatment of nematodes in raptors at the dose rate of 10 to 20 mg/kg PO for 2 consecutive days. 47 Alternatively, fenbendazole at the dose rate of 25 mg/kg PO for 5 consecutive days has been suggested.²⁹ Ivermectin also has been widely used for the treatment of nematode infections, in particular those involving Serratospiculum seurati^{46,85} in the Middle East. Ivermectin at the dose rate of 200 μg/kg IM or SC has been used to stunt the parasites and allow subsequent surgical removal of adult worms. 46,85 However, doses of up to 3 mg/kg IM have been suggested for the control of *S. seurati* infections in hybrid gyrfalcons. 46 The author, in common with other clinicians, has found that ivermectin at the dose rate of 2 and 3 mg/kg IM or SC can lead to temporary blindness lasting up to 48 hours in saker, peregrine, Barbary (Falco pelegrinoides) and lanner falcons.85 The author favors the use of moxidectin^p at the dose rate of 1 mg/kg

PO q7d x 2 weeks, for the treatment of *Serratospiculum* seurati, *Capillaria falconis*, *Physaloptera alata* and acanthocephalan infections in falcons (Figs 40.44-40.45).

Microparasites

Protozoa

Trichomonas gallinae is perhaps the single most important protozoan affecting raptors worldwide. The disease, known in falconry terminology as frounce, is typically characterized by the appearance of caseous lesions in the upper digestive system, including the tongue, oropharynx, crop and esophagus⁹³ (Fig 40.46). Trichomoniasis also can affect the upper respiratory tract of raptors, affecting the nasal cavities, the infra-orbital sinuses, the trachea and the tracheobronchial syrinx. 79,93 Carnidazole^q, at the dose rate of 20 mg/kg PO10 to 120 mg/kg PO100 as a single dose, has been used in the treatment of clinical trichomoniasis in raptors. Conversely, metronidazole can be used at the dose rate of 50 mg/kg PO SID for 5 consecutive days.93 Currently, the author uses metronidazole at a higher dose, 100 mg/kg PO for 3 consecutive days, in the treatment of trichomoniasis in falcons, as this appears to be more effective (Figs 40.47-40.52).

Several different species of coccidia of the genera Caryospora, Eimeria, Sarcocystis and Frenkelia (Table 40.19) are relevant in raptor medicine. 42,44 Species of the genus Caryospora appear to be the more pathogenic to raptors, particularly to young birds under captive conditions. Weight loss, reduced appetite, regurgitation and vomiting, blood in feces, diarrhea and acute death characterize clinical coccidiosis.¹⁹ Similar clinical signs, together with poor performance during training exercise, have been frequently observed by the author in captive falcons in the Middle East, particularly in juvenile peregrine, Barbary and lanner falcons. The treatment of choice for coccidiosis is toltrazuril^s 25 mg/kg PO.⁴⁰ This product is known to have a bitter taste and tends to induce regurgitation in a significant number of raptors immediately after administration. The author administers toltrazuril with a crop cannula to falcons at this dose rate, mixed 1:1 with a cola-based soft drink to mask its bitter taste, for 2 consecutive days. The incidence of regurgitation is significantly reduced with this method.

Table 40.19 | Common Microparasites of Raptors

Coccidia	Caryospora kutzeri, C. boeri, C. henryae, C. falconis, C. megafalconis, C. neofalconis, C. uptoni, C. buboni, Frenkelia microtis, F. glareoli Sarcocystis cernae, Eimeria accipitris, E. asturi
Hematozoa	Haemoproteus tinnunculus, H. brachiatus, H. elani, H. nisi, H. janovyi, H. syrnii, Plasmodium elongatum, P. fallax, P. circumflexum, P. lophurae, P. relictum, P. vaughani, Leucocytozoon toddi, L. ziemanni, Trypanosoma bramae, T. noctuae, T. santodiasi, T. syrnii, T. avium, T. fiadeiroi, T. guyanense, T. langeroni, T. everetti, T. fiadeiroi, T.corvi

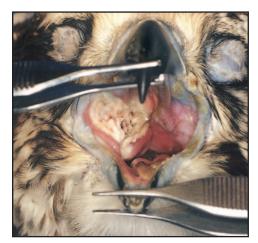

Fig 40.46 | A large caseous lesion produced by infection with the protozoan *Trichomonas gal*linae in the lateral oropharynx of a saker falcon. Infection usually occurs when captive raptors are fed pigeons or doves. Raptors living in urban or suburban areas are prone to contract trichomoniasis because they have access to feral populations of pigeons.

Hematozoa

Hematozoa (Greek: baima = blood, zoa = animals) are protozoan parasites living in the blood. The most relevant species in raptor medicine (Table 40.19) are classified under the genus Haemoproteus, Leucocytozoon, Plasmodium and Trypanosoma. 42,44,59 There appears to be a relatively high incidence of some hematozoa in free-living birds. In a recent survey, up to 11% of 976 Falconiformes and up to 13% of 173 Strigiformes were found positive for hematozoa in Germany.43 The impact of these hemoparasites on their host is not well understood. In general terms, it is believed that the pathogenicity of most hemoparasites for raptors is relatively low. However, hematozoa infections have been directly implicated in severe clinical disease and even the deaths of individuals. It has been shown that infections with P. relictum can cause severe clinical disease in gyrfalcons, while several deaths in nestling owls have been attributed to Parabaemoproteus¹⁰¹ spp. and Leucocytozoon spp. infections.³² In addition, the deaths of a sub-adult saker falcon91 and a common kestrel (Falco tinnunculus)56 were attributed to severe hypochromic anemia produced by heavy parasitic infections of Babesia shortti.

Suggested treatment for hematozoa includes the use of chloroquine^t at the initial dose rate of 25 mg/kg PO, followed by 15 mg/kg at 12, 24, 48 hours together with primaquine^t at the dose rate of 0.75 mg/kg PO.^{29,31}

BACTERIAL DISEASES

There are numerous bacterial diseases that have been described in different species of raptors worldwide. A brief description is therefore included here of the most

Fig 40.47 | Unilateral trichomoniasis infection in the nasal cavity of a saker falcon. The caseous mass is bulging through the palate. This type of infection very often leads to moderate to severe obstruction of the nasal cavity and difficulty eating. Note the food debris accumulated at the cranial aspect of the palate. In extreme cases, this condition could lead to a fistula formation between the oral and nasal cavities.

Fig 40.49 | The same falcon as in Fig 40.48 after treatment and 2 weeks after surgery. The falcon was administered metronidazole for 3 consecutive days and an antibiotic for 7 days, after which time the caseous masses were surgically removed.

Fig 40.51 | An extreme case of trichomoniasis infection in a saker falcon. The appearance in this falcon is misleading, as it gives the impression that it had just eaten and has a full crop.

Fig 40.48 | Severe unilateral trichomoniasis infection affecting the supraorbital region of a saker falcon. The infection usually enters through the supraorbital diverticulum of the infraorbital sinus. Note the large, multiple caseous masses bulging through the skin.

Fig 40.50 | Multiple nodular trichomoniasis lesions at the cranial aspect of the thoracic esophagus as seen from the crop. The masses had created a virtual ring, producing stenosis. The growths were not palpable from the crop, therefore illustrating the need to examine the upper digestive tract by endoscopy in selected cases based on the clinical history.

Fig 40.52 | A dorsoventral radiograph of the same falcon as in Fig 40.51, clearly showing a single large caseous mass within the crop. In most cases, masses such as this can be retrieved through the oropharynx after a course of antiprotozoal therapy.

frequently reported conditions. For a comprehensive review of bacterial diseases in raptors, the reader is referred to a recent publication on this subject.9

Tuberculosis is a bacterial disease produced by Mycobacterium avium avium. This condition is considered rare in North American raptors⁶⁵ but is frequently found in the United Kingdom and continental Europe. 9,29 The disease is characterized by the presence of tubercles primarily in the liver, spleen, gastrointestinal tract and bones. Subcutaneous tubercles also have been described in raptors. 9,29 Diagnosis with the tuberculin test is unrewarding.29 The use of radiology in bone-related infections has proved useful.65 For a more accurate diagnosis, suspected birds should be subjected to endoscopic examination and subsequent liver biopsy and histopathology analysis. Treatment of tuberculosis is not recommended in raptors, particularly when the birds are in close contact with humans; but if treatment is deemed appropriate, a number of therapeutic agents have been proposed.⁷ The treatment protocol should run parallel to an adequate biosecurity program targeted at containing the disease (see Chapter 28, Implications of Mycobacteria in Clinical Disorders).

The gram-negative microorganism Chlamydophila psittaci, produces chlamydiosis. This microorganism has been detected serologically in both captive15,22 and freeliving raptors,21 but very few cases of actual clinical chlamydiosis have been recorded in the literature. 15,54 The disease is characterized by unilateral or bilateral periocular swelling and conjunctivitis, rhinitis and lime green-colored urates.15 Suggested treatments include the administration of doxycycline at the dose rate of 50 mg/kg BID PO for 45 days¹⁵ or 100 mg/kg IM every 5 days for a total of six doses,²⁹ or azithromycin at 40 mg/kg once a week PO for up to 4 weeks102 (see Chapter 27, Update on Chlamydophila psittaci).

There are very few reports in the literature on the incidence of clostridial enterotoxemia in raptors. 108 This disease is produced mainly by Clostridium perfringens type A/B, although C. bistolyticum also has been implicated on a single occasion. 108 Clostridium perfringens is characterized by the production of potent toxins that are readily absorbed from the gastrointestinal tract, resulting in severe illness and death. Mismanagement of food items before and after freezing has been blamed as a possible cause for the proliferation of the microorganism. 29,108 In addition, the management system used widely by falconers - providing meat soaked overnight in water to falconry birds — has been proposed as a potential risk for the proliferation of C. perfringens.29 In most cases of infection, the course of disease is peracute or acute. In peracute cases, death occurs after a relatively short period of

Fig 40.53 | Pseudomonas aeruginosa stomatitis as a sequel to a recent trichomoniasis infection. Note the characteristic multiple caseous masses present in the caudal and lateral aspects of the oropharynx and on the tongue. In most cases, the tongue is grossly enlarged, preventing birds from eating normally.

general depression. In acute cases, clinical signs include general depression, reduced appetite, regurgitation, soft brown feces progressing rapidly to reddish and hemorrhagic, pastel green-colored urates and recumbency.²⁹ Suggested treatments for the acute form include the use of oxytetracycline at the dose rate of 100 mg/kg SID for 5 days or a single dose of a doxycycline long-acting preparation at the dose rate of 100 mg/kg.29 Three falcons that displayed typical clinical signs of clostridial enterotoxemia survived after the administration of a bovine polyvalent gangrene antiserum IV.108

Pseudomoniasis is an infectious disease produced by the rod-shaped, gram-negative bacterium Pseudomonas aeruginosa. In avian species, P. aeruginosa is considered to be an opportunistic pathogen and seldom is considered the primary source of infection. 12,23 Pseudomonas aeruginosa is commonly associated with upper respiratory tract infections in psittacine birds⁶⁰ and is often isolated from respiratory tracts of juvenile ostriches.12 It is believed that predisposing factors such as injuries to mucosal membranes, general weakness produced by systematic diseases, immunosuppression and reduced normal flora might lead to infections with P. aeruginosa.60 Recently, stomatitis produced by P. aeruginosa as a sequel to trichomoniasis was described in falcons in the Middle East. 80 The disease was characterized by the presence of small, nodular, white-yellow caseous masses, ranging in size from 2 to 5 mm distributed across the oropharynx (Fig 40.53). In addition, the tongue displayed numerous nodular masses distributed across the dorsal and lateral aspects, varying in size from 0.5 to 5.0 mm, resulting in a gross enlargement of the tongue to the extent that the falcon could not close its beak.80 Treatment includes administering antibiotics such as piperacillin and amikacin or tobramycin in combination, daily

curetting of caseous masses and the application of oral antiseptics.

There have been reports in the literature of bacterial findings during microbiology surveys in raptors. Some of the bacteria isolated probably can be considered normal or transient flora, and therefore their presence will not necessarily result in disease. For instance, the culture of some bacteria, such as Pseudomonas spp., from infected wounds is relatively common, but is not necessarily involved in the infectious process.9 One such finding includes Mycoplasma in different species of free-living raptors 49,50 and captive falcons in the Middle East. 48 However, as previously stated, "Today's commensal is tomorrow's pathogen".9 Under some circumstances, some bacteria might be pathogenic due to immunosuppression and stress, resulting in clinical disease. For instance, mycoplasmosis was recently diagnosed in a free-living saker falcon nestling affected with skeletal deformity due to perosis.14 Other bacteria that have been implicated in clinical disease include Pasteurella multocida,55 Salmonella enteriditis, S. typhimurium, 16 Campylobacter jejuni, 16 Yersinia pseudotuberculosis, 16 Escherichia coli9 and Staphylococcus aureus.9

VIRAL DISEASES

The most significant viral diseases in raptors include Newcastle disease, avian pox and raptor herpesvirus infection.

Newcastle disease is an infectious viral disease produced by avian paramyxovirus serotype 1.53,71,104,107 In falcons, the disease is characterized by gastrointestinal signs in the earliest stage of the disease, followed by central nervous system signs including ataxia, head tics and tremors, and wing and leg paralysis. 107 Annual vaccination with inactivated vaccines is highly recommended. 9,29,106 A vaccine derived from local strains in the Middle East has been used successfully in different species of birds including falcons.107

Avian pox is a viral disease known to affect captive^{37,82} and free-living raptors.95 The interrelationship of the different strains is not clearly understood. Pox infections in raptors are not considered fatal. However, the loss of an eye due to scratching, the loss of digital function due to avascular necrosis of digital tendons and the sloughing of talons due to distal necrosis are very often observed. In addition, pox infections on the cere can lead to permanent damage to the nostrils, the nasal septum, conchal structures and, in extreme cases, to avascular necrosis of the nasal bridge (Figs 40.54, 40.55). Treatment of early-stage lesions consists of cauterizing, debriding the upper layer and application of alcohol-based antiseptic solutions (eg, merthiolate, mercurochrome or iodine).

This treatment tends to arrest the development of firststage lesions into scabs. Scabs are best treated only with antiseptic solutions. The addition of glycerol or liquid paraffin wax to the antiseptic solution is beneficial. Scabs on the cere are treated by surgical removal and the periodic application of hydrocolloidal dressings86 (Figs 40.56-40.59). Diagnosis of the disease is possible by identifying the virus at electron microscopy or by detecting the presence of Bollinger's intracytoplasmatic bodies in cytologic or histologic preparations of the skin of affected individuals. 104 Annual vaccination with commercially available live vaccines has been suggested.¹⁰⁴ Recently, a new strain of the virus was isolated from falcons in the Middle East, and studies are under way to develop a more species-specific live vaccine.5

Raptor herpesvirus infection is a disease that affects captive and free-living Falconiformes and Strigiformes.²⁴ Three distinct species of the virus have been identified to date including Falconid HV1, Strigid HV1 and Accipitrid HV1.24,104 Affected individuals invariably die within 2 or 3 days after manifesting signs, including anorexia, pastel green-colored urates and general depression. The infection produces widespread characteristic white-yellow necrotic foci in the parenchyma of the liver and spleen²⁹ (Fig 40.60). Considerations for the production of a vaccine have been extensively discussed. 67,68 Recently, an attenuated vaccine has been produced and used successfully in common kestrels.105

Other viral infections affecting raptors worldwide include the West Nile virus,98 avian influenza51 and avian polyomavirus.³⁶ A comprehensive review of the viral diseases affecting raptors has been published elsewhere9 (see Chapter 32, Implications of Viruses in Clinical Disorders).

FUNGAL DISEASES

Aspergillosis is the most common infectious disease affecting captive raptors. 63 The disease is caused mainly by Aspergillus fumigatus, although other fungi of the same genus, such as A. flavus and A. niger, also have been implicated. 9.29 Some species appear to be more susceptible than others to contracting the disease. For instance, raptor species that have been identified as prone to contract aspergillosis in captivity include the golden eagle (Aquila chrysaetos), goshawk (Accipiter gentilis), gyrfalcon (Falco rusticolus), immature redtailed hawk (Buteo jamaicencis) and snowy owl (Nyctea scandiaca). 63 Aspergillosis is usually contracted through heavy or mild spore inhalation over a period of time, together with factors that compromise immune function. Examples of these factors include recent capture, poorly ventilated quarters, neonatal and geriatric conditions, corticosteroids, exposure to respiratory irritants and lead toxicosis. 63 After exposure, the disease might follow

Fig 40.54 | A large scab on the cere of a saker falcon produced by an infection with avian pox. Note that the naris is completely obstructed. The removal of the scab and application of hydrocolloid dressings is indicated. Complete healing has been achieved in 2 to 3 weeks following this technique.

Fig 40.55 | Avian pox infection on both feet of a peregrine falcon. Note that the lesions are still in the pustular stage. The electrocauterization of such lesions and the application of an alcoholbased antiseptic are indicated. The primary objective of such therapy is to prevent the development of scabbing.

Fig 40.56 | Early stage of the development of pox infection in a male saker falcon. Note that the eyelids and the cere are equally affected. Pox infections in the Middle East follow a seasonal pattern and are relatively common during the spring.

Fig 40.57 | A pustular-type pox lesion on the commissure of the mouth of a saker falcon. This type of lesion is relatively rare in raptors.

Fig 40.58 | A large fistula in the commissure of the mouth of a saker falcon created by the presence of a large pox scab. Prompt and effective treatment is required in order to arrest the development of early lesions into scabs in this anatomical site. Surgical reconstruction of the mouth is indicated in this type of presentation.

Fig 40.59 | An unusual nodular growth produced by avian pox on an apterium of the neck of a saker falcon. The dry type of avian pox infection tends to develop in unfeathered areas of the body, mainly on the cere, eyelids, tarsus and digits. These dry lesions are infrequently observed on other anatomical sites.

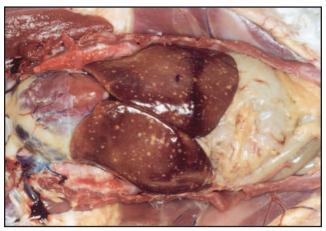

Fig 40.60 | Herpesvirus infection in a saker falcon. The liver is slightly enlarged. Note the presence of characteristic multiple necrotic foci disseminated across the liver. The bird was presented with a history of anorexia and passing pastel greencolored urates.

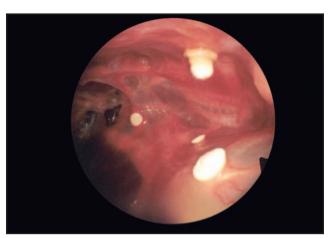

Fig 40.61 | Early lesions of aspergillosis in the coelomic cavity of a saker falcon. Stress associated with overexertion and recent capture, exposure to decaying vegetable matter and immunosuppression have all been implicated in the development of this fungal disease. Some raptor species appear to be more susceptible to developing the disease.

Fig 40.62 | Large aspergilloma in the coelomic cavity of a saker falcon as observed on a ventrodorsal radiograph. It is very common for raptors to develop a single, large aspergillosis lesion.

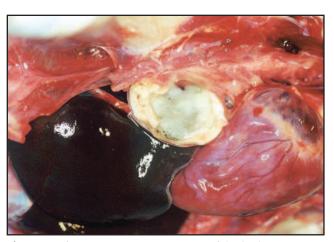

Fig 40.63 | A postmortem examination of the bird in Fig 40.62. Note the size and location of the already sectioned aspergilloma showing sporulating fungal colonies of Aspergillus fumigatus.

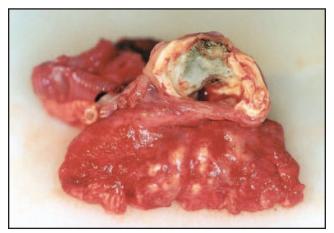

Fig 40.64 | A dissection of the aspergilloma and the lungs of the bird in Figs 40.62 and 40.63. Note the numerous smaller aspergillomas developing in the lungs.

Fig 40.65 | Unilateral obstruction of one primary bronchus in a saker falcon produced by infection with Aspergillus fumigatus. Severe bilateral obstruction requires the placement of an air sac cannula to alleviate dyspnea.

an acute or a more chronic course depending on exposure and immunosuppression. The acute form is characterized by the development of extensive miliary granulomas throughout the lungs. The more chronic forms might include the development of small to large granulomas mainly in the tracheobronchial syrinx, pericardium, lungs and air sac system⁶³ (Figs 40.61-40.65). At the onset of the disease, clinical signs typically include subtle changes in behavior, reduced appetite, shredding and flicking of food, lack of stamina and decreased flight performance. Respiratory signs including dyspnea, wet rales and change of voice, and usually follow behavioral changes. Diagnosis is made through a detailed clinical history, tracheal and air sac swabs submitted for cytologic examination and culture, endoscopy examination, hematology, enzyme-linked immunosorbent assay (ELISA) and antigen capture test. 63 Treatment typically consists of itraconazole^u PO at the dose rate of 5 to 10 mg/kg BID for 5 days then decreased to q24h for 2 to 3 months, amphotericin B^v intratracheally (IT), 1 mg/kg diluted to 1 ml volume BID for 5 days, and nebulization with clotrimazole for 1 hour BID for 2 to 3 months.63 Surgery is usually recommended to remove aspergillomas located at the syrinx and within the coelomic cavity. A 1:10 solution of enilconazole w 0.5 ml/kg BID intratracheally (IT) and nebulization with a 1:10 dilution for 20 minutes QID also have been recommended.¹⁷ Recently, nebulization with a quaternary ammonium and biguanadine compound disinfectantⁿ has been proposed. 4,103

Candidiasis, or thrush, is a fungal disease produced primarily by the yeast Candida albicans. The disease is usually endogenous in origin and can be triggered by predisposing factors including immunosuppression, stress, prolonged use of antibiotics and nutritional deficiencies.⁵⁷ In raptors, candidiasis is characterized by the presence of amorphous diphtheritic membranes that are whitish gray to gray-green in color and affect mainly the crop88 (Fig 40.66). There are several other diseases that affect the upper digestive tract in raptors. These include vitamin A deficiency, Pseudomonas aeruginosa stomatitis, trichomoniasis and capillariasis. The importance of establishing a complete list of differential diagnoses prior to instituting therapy is stressed.88 Raptors affected with candidiasis demonstrate clinical signs including reduced appetite or anorexia, shredding and flicking of food, regurgitation and progressive weight loss.88 The diagnosis is suggested through the clinical history and observation via endoscopic examination of the characteristic "Turkish towel" appearance of the crop. The blastospores of *C. albicans* can be demonstrated in stained cytological preparations obtained from affected areas. Traditionally, the treatment of candidiasis in raptors has included nystatin, ketoconazole, itraconazole or fluconazole. Topical use of a miconazole preparation^x applied BID for 3 to 5 days has recently

Fig 40.66 | Infection with *Candida albicans* in the crop of a saker falcon. Candidiasis is often associated with immune depression, delay in emptying of the crop and nutritional deficiencies. Note the typical "Turkish towel" appearance of the mucosal membrane of the crop.

been described⁸⁸ (see Chapter 29, Implications of Mycoses in Clinical Disorders).

Non-infectious Diseases

Non-infectious diseases include a diverse group of medical conditions caused by a single or multifactorial etiology. While for some of these conditions the etiology is clearly understood, such as in the case of metabolic bone disease, the causes of others such as amyloidosis are not known.

Palpation of the pectoral muscles, weighing the bird and assessing its behavior are commonly performed to determine body condition in captive raptors. The assessment of pectoral muscle mass on its own is not a reliable indicator of body condition, as most of the body fat is deposited within the coelomic cavity, under the wings around the scapular areas and in the lower abdomen. The best way of assessing body condition in captive raptors is a combination of the three parameters mentioned above.

METABOLIC BONE DISEASE

Metabolic bone disease is a term that encompasses a series of medical conditions that affect mainly the mineralization of bones, including osteoporosis, osteomalacia, rickets, fibrous osteodystrophy and nutritional secondary hyperparathyroidism. These conditions are usually related to mineralization disorders of the osteoid due to Ca and/or vitamin D₃ deficiencies. Other diseases affecting the growth, mineralization, maturation and maintenance of bone include the twisting and bending of long bones and slipped tendon, which are commonly seen in fast-growing birds.³⁹ Correct diet, adequate feeding management and vitamin/mineral supplementation are

essential in breeding raptors in captivity.²⁹ Excellent analysis and recommendations for raptor nutrition have been published elsewhere.¹⁸ (*Ed. Note: While the Author does not do so, this reference advocates day-old chicks which may have an acceptable Ca:P but there is insufficient calcium. At the University of Guelph they fed chicks to growing Northern Harriers and they all developed metabolic bone disease*). Treatment is usually indicated and includes changes in the diet and vitamin/mineral supplementation.²⁹ However, individuals already exhibiting folding fractures and severe bending of long bones should be humanely destroyed, as treatment is seldom successful.

Disorders of the Digestive System

SOUR CROP

Sour crop in raptors is a medical emergency condition caused by the retention of food in the crop, resulting in content decomposition leading to rapid bacterial proliferation, septicemia and death. The condition might result simply from over-feeding. This is a common occurrence in falconry birds when enthusiastic falconers allow a particular bird to gorge itself to rapidly increase the body weight. Factors that might influence crop stasis include low body condition, gizzard impaction with casting or foreign material, or general disease. Usually birds with sour crop are presented in a state of endotoxic shock with a swollen crop that is filled with macerated and foul-smelling, decomposing food. Affected birds tolerate general anesthesia with isoflurane very well. An endotracheal tube should be placed carefully to avoid aspiration pneumonia. Gently massaging the crop contents toward the mouth and retrieving this material with blunt-tipped forceps should remove the food. Extreme care should be exercised during the massaging process to avoid lacerations or penetrating wounds to the crop if there are bones present in the crop. In extreme cases, an ingluviotomy can be performed to remove impacted contents. After removal of the decomposing food, a tube should be passed down to the proventriculus, and approximately 50 ml/kg of 0.1% chlorhexidine or 1:1000 of quaternary ammonium and biguanadine compounds disinfectantⁿ solution can be flushed to decrease the bacterial load present in the upper GIT. The author favors the use of marbofloxaciny 15 to 20 mg/kg PO or IM for 3 to 5 days SID in the postoperative care of sour crop. Depending on the bird's condition, force-feeding might be necessary for 2 to 3 days. An excellent account of the medical management of sour crop has been previously described.61

Fig 40.67 | Ventrodorsal radiograph of a saker falcon showing the presence of foreign material in the gizzard. The ventriculus was repeatedly flushed retrieving a large amount of red desert sand. The bird was presented with a history of delay in emptying the crop, reduced appetite and progressive weight loss.

GASTROINTESTINAL FOREIGN BODIES

Gastrointestinal tract (GIT) foreign bodies are a relatively common occurrence in raptors. One of the most significant findings includes lead pellets or lead fragments in the GIT, usually the ventriculus, of raptors fed on shot prey. A full account of the diagnosis and management of lead toxicosis will be addressed later in this chapter. Other foreign materials that have been found include grass, synthetic strands from artificial turf, sand and grit (Fig 40.67). In general, these are materials that tend to adhere to the offered food when it falls on the ground. Small quantities of these materials are usually cast out (grass, artificial turf strands) or passed out with fecal material (sand and grit). However, large quantities of foreign material can significantly reduce the capacity of the proventriculus and ventriculus or cause impaction in these sites.

Falconry birds appear to be the most commonly affected. In the Middle East, it is very common to be presented with a falcon with a history of reduced appetite or complete anorexia, delayed crop emptying and regurgitation. Radiographically, large amounts of sand and mediumsized grit have been observed in the ventriculus. In some cases, it has been estimated that approximately 50 to 75% of the total capacity of the ventriculus has been occupied by foreign material. In one case involving a wild-caught gyrfalcon, the ventriculus and proventriculus were completely impacted with grass. This bird died before any treatment could be instituted. The wet weight of the grass retrieved from the ventriculus was 40 g. It also is

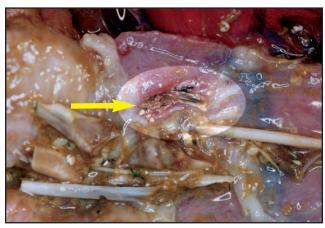

Fig 40.68 | A unusual case of a penetrating wound on the wall of the gizzard of a saker falcon caused by a sharp, bony splinter (arrow). The bird died of acute peritonitis. Other bone fragments with sharp edges also are present. Under normal circumstances, bones are cast out the following day after a meal. However, entire long bones (eg, femur) should be not be offered to captive raptors.

Fig 40.69 | Severe sinusitis and associated conjunctivitis in a saker falcon. Note the large amount of clear discharge originating from the nares and the nasolacrimal duct. Sinusitis may be the result of systemic (eg, chlamydiosis), localized infections (eg, trichomoniasis) or secondary bacteria.

common to find large amounts of impacted casting material (fur, feathers, bones). Retrieval of foreign material from the gizzard can be attempted by ventricular lavage. For large falcons (1.0 to 1.5 kg), the author favors stomach tubes commonly used to feed neonatal lambs. This procedure should be undertaken with the bird under isoflurane anesthesia. The placement of an endotracheal tube is essential to avoid aspiration. The stomach tube is lubricated with water-soluble gel¹ and passed gently into the gizzard. A 60-ml syringe is then attached to the tube and the stomach is flushed repeatedly with warm (32-35° C) water. The quantity of water used depends on the amount of foreign material present. Usually, 180 to 240 ml is sufficient to dislodge all material. In severe cases of ventricular impaction, surgical removal of foreign bodies is indicated. The author has used a rigid endoscope and 33 cm long modified grasping forceps, to remove casting material, lead pellets and other foreign bodies from the gizzards of falcons (Fig 40.68).

Disorders of the Respiratory System

Rhinitis is the inflammation of the mucosal membrane of the nasal cavities, which may be due to the presence of foreign bodies, rhinoliths, trichomoniasis or bacterial invasion (Fig 40.69). Captive falcons have the tendency to face the wind while tethered out in the open. Sand storms are relatively common in the Middle East during the training and hunting season. Very often, fine dusty sand finds its way into the nares, producing mechanical occlusion within the nasal cavities.⁷⁴ Trichomoniasis and associated invading bacteria affecting the nasal cavities of

captive falcons have been previously described.93 The only clinical sign usually observed is fluttering of the skin immediately above the affected nares. In severe and chronic cases, the presence of foreign material and rhinoliths, and complete obstruction of the nares is obvious on physical examination. Treatment consists of the manual removal of obstructing debris with a fine blunt probe or a pair of fine-tipped round forceps, together with the instillation of saline drops. Sometimes, several sessions are required to remove all foreign material. Flushing the nasal cavities of affected individuals is highly recommended, as this tends to dislodge foreign material more efficiently (Figs 40.70-40.72). In severe or chronic cases, partial retrieval of foreign material before flushing is often necessary. The flushing solution is usually prepared with an antiseptic (chlorhexidine 50 ml/kg of 0.1%) or an antibiotic (enrofloxacin or marbofloxacin) in normal saline. The author favors a 1:250 solution with quaternary ammonium and biguanadine compoundsⁿ. Construction of a device for flushing the nares of affected falcons has recently been described in the literature.81

Sinusitis is the inflammation of the infraorbital sinuses, produced mainly by invading bacteria. In most cases, sinusitis is produced as a sequel to rhinitis caused primarily by obstruction and subsequent proliferation of bacteria. Supraorbital trichomoniasis infection was recently described in saker falcons. ⁷⁹ Intranasal flushing with antibiotics or antiseptics has some effect in mild cases. However, intrasinal injection of solutions such as those used for rhinitis is highly recommended. Strict aseptic and sterile measures should be observed when injecting into the sinus. The use of antibiotics such as marbofloxacin 15 to 20 mg/kg PO, IM SID for 5 to 7 days is indicated.

Fig 40.70 | One of the most effective collateral treatments in the therapeutic management of rhinitis and sinusitis is the systematic flushing of antiseptic, disinfectant or antibiotic solutions through the nares of affected individuals. The equipment commonly used to clean the nares and to flush the nasal cavities is shown here.

Fig 40.72 | A nasal flushing of a saker falcon in progress. Large syringes (eg, 20 ml) fitted with a small rubber plunger at the end are useful for this procedure. Note that the falcon has been wrapped with a towel in order to avoid damage to the feathers.

Fig 40.71 | Small round-tipped probes are very useful to remove rhinoliths from the nares and relieve obstructions. It is important to soak rhinoliths with saline solution drops during the removal process. Extreme care must be exercised to avoid injuries to the concha.

Fig 40.73 | Amyloidosis and related ascites in a saker falcon. The etiology of amyloidosis in raptors is poorly understood. Therapeutic management of amyloidosis is still in its infancy. Some success has been obtained by removal of the ascitic fluid and the administration of glucose and ascorbic acid, and general support therapy.

Non-infectious Diseases

Amyloidosis (Greek: Amylon = starch, eidos = form) is a disorder affecting primarily the liver, although the spleen, kidneys and even the brain99 can be involved. The condition is characterized by the deposition of amyloid within the parenchyma of the liver, engulfing and obliterating the hepatocytes.³⁰ Amyloid deposition appears to be stimulated by chronic disease involving antibody-antigen production, such as aspergillosis, bumblefoot or tuberculosis. However, the author has encountered several mild to severe cases of amyloidosis in falcons with no previous history or evidence of disease. It is possible, therefore, that subclinical disease might also stimulate deposition of amyloid in the liver. Nutrition or nutritional management also may play an important role, as the majority of cases

seen by the author have been in falcons that have undergone dietary changes such as the removal of one of the main food items (eg, day-old chicks) several weeks before the onset of disease (Fig 40.73).

Disorders of the **Nervous System**

There is a series of disorders involving the nervous system in captive raptors, produced by nutritional deficiencies, infectious diseases, toxicosis and lesions of the central and peripheral nervous systems.9 For a comprehensive review of the different neurological disorders affecting raptors, the reader is referred to a recent publication.9 However, an account of some of the most

recently described disorders and those commonly observed by the author in falcons in the Middle East is presented here.

Progressive paralysis of the hind limbs might be the result of lead toxicosis, botulism (G. Harrison, personal communication, 2003), aspergillosis, kidney disease, trauma, arthritic changes in the vertebral synsacral joint due to trauma, 25 Newcastles disease 107 and atypical parasitic migration.28 The latter finding might be a more common occurrence that has gone largely undiagnosed in geographical areas, including the Middle East, where parasitic infections with different species of the genus Serratospiculum are very common. Fish-eating raptors such as the osprey, fed frozen/thawed fish, require supplementation with thiamine (vitamin B₁) as part of dietary management to avoid paralysis of the hind limbs.65 In addition, lumbosacral plexus avulsion has been suspected in tethered falcons presented with unilateral paresis or paralysis. Some of these cases have responded well to non-steroidal anti-inflammatory agents such as meloxicam² (0.1 mg/kg SID PO or IM for 3 to 5 days) and administration of 25 mg/kg vitamin B₁^{aa} IM for 3 to 5 days or 25 mg/kg vitamin B₁^{bb} PO for the same period or longer. Stargazing, convulsions and seizures have been observed in captive raptors, primarily in falcons²⁹ (Figs 40.74, 40.75).

In the Middle East, falcons are commonly presented with CNS signs including moderate to severe tilting of the head or opisthotonos. These signs are exacerbated when the hood is in place. In severe cases, these falcons might even fall backward from the perch when disturbed. In addition, falcons are often presented with a history of having experienced a "fit during a training session or while simply standing on the perch". The etiology might be multifactorial, but deficiencies of B-vitamin complex29 and vitamin E9 have been implicated. In such cases, the author favors administering 1 ml/kg IM of a multivitamin preparation (providing 15,000 IU vitamin A, 25 μ g vitamin D₃, 20 mg vitamin E, 10 mg vitamin B₁, 5 mg vitamin B₂, 25 μg vitamin B₁₂, nicotinamide 35 mg, 25 mg d-panthenol^{cc}). This is usually followed by administering PO tablets of a multivitamin preparation^{dd} (providing 2000 IU vitamin A, 250 IU vitamin D₃, 5 IU vitamin E, 2 mg vitamin K, 10 mg niacin, 2.5 mg pantothenic acid, 0.4 mg iodine, 1 mg vitamin B_1 , 8 μ g pyridoxine, 0.1 μ g vitamin B_{12} , 0.5 mg folic acid, $80 \mu g$ choline bitartrate, $0.2 \mu g$ biotin, 0.4 mgriboflavin) administered directly or within the food for 1 or 2 weeks, in powder form (containing per 1 g 1000 IU vitamin A, 125 IU vitamin D₃, 2.5 IU vitamin E, 1 mg vitamin K, 5 mg niacin, 1.2 mg pantothenic acid, 1.2 mg riboflavin, 0.4 mg vitamin B_1 , 0.4 mg pyridoxine, $0.5 \mu g$ vitamin B₁₂, 0.2 mg folic acid, 0.4 µg choline bitartrate, 0.1 μ g biotin, 2 μ g iodine) administered daily in drinking

Fig 40.74 | Saker falcon presented with severe torticollis. The problem was present only when the bird had its hood in place. Severe torticollis may lead to falcons falling from the perch due to loss of balance. The etiology of this condition is believed to be the result of vitamin B complex deficiency.

Fig 40.75 | Saker falcon displaying opisthotonos, a common central nervous sign associated with vitamin B complex deficiency in raptors.

Fig 40.76 | Unilateral flaccid paralysis of the foot in a saker falcon. The etiology of this condition is not clearly understood, but avulsion of the nervous plexus or injury to individual nerves has been suggested as the possible cause.

water for 1 or 2 weeks. Success in treating such cases appears to be related to how promptly the treatment is instituted. Recovery and full cessation of clinical signs have been observed when treatment was administered within 24 to 48 hours after the initial signs were noticed. However, the etiology of this and other diseases remains unclear and there is, therefore, a need to conduct further research into the etiology, diagnosis and pathogenesis of neurological disorders affecting raptors (Fig 40.76) (see Chapter 4, Nutritional Considerations).

Disorders of the Eye and Ear

Conjunctivitis is the inflammation of the membrane that lines the eyelid and the exposed surface of the sclera, characterized by hyperemia and, in severe cases, discharge. The condition in raptors is usually associated with the presence of foreign bodies such as feather particles, sand or dust. Foreign material also can be lodged under the nictitating membrane or lower eyelid. If the presence of foreign material is suspected, the bird should be examined under general anesthesia and the eye repeatedly flushed with normal saline solution or a proprietary eye solutionee and any visible foreign material removed with the aid of sterile cotton swabs. The treatment of conjunctivitis might include ophthalmic drops^{ff} BID for 3 to 5 days. In more severe cases and in the presence of inflammation, the use of corticosteroid (betamethasone) and antibiotic (neomycin) drops^{gg} BID for 2 to 3 days might be considered.

Corneal lacerations and keratitis are probably the most common types of injuries seen in raptors. Most of the injuries are caused by trauma. Lacerating wounds to the cornea are often observed in falcons in the Middle East. Falcon trappers use a procedure called "sealing" to tame newly caught free-living falcons. The procedure consists of placing a stitch on the proximal edge of the lower eyelids with a standard stitching needle and a fine cotton thread. The two threads are then secured with a knot on the top of the head to close shut or "seal" the eyes. During the process it is very common to produce penetrating wounds and lacerations to the cornea while stitching. Mild to severe injuries to the cornea usually benefit from temporary tarsorrhaphy and the use of antibiotic eye drops.⁵⁸ Corneal injuries also can result when one of the laces used to close and open the hood is inadvertently left inside and in direct contact with the eye. The use of fluorescein stain in the assessment of the integrity of the cornea is recommended, as eye drops or ointments containing corticosteroids should not be used in the presence of corneal lacerations since these might delay healing.

Uveitis is the inflammation of the vascular middle area of the eve including the iris, ciliary body and choroid. Uveitis and tears in the iris are commonly seen in raptors involved in collision accidents and trauma to the head.38 Mild to severe cases of uveitis can be resolved successfully with the use of a non-steroidal anti-inflammatory agent such as meloxicam^z at the dose rate of 0.1 mg/kg SID PO or IM for 5 to 7 days, and the instillation of corticosteroid and antibiotic drops^{gg} BID for 2 to 3 days.

Otitis is the inflammation of the ear and is relatively rare in raptors. In falcons, otitis is usually produced by the presence of foreign material, ectoparasites or trichomoniasis. Affected individuals usually present with a mild to severe head tilt, feather matting and a thick purulent discharge around the ear opening. The treatment of otitis consists of removing caseous and purulent material with normal saline and cotton swabs and the instillation of corticosteroid and antibiotic drops^{gg} BID for 3 to 5 days. Trichomoniasis should be treated with metronidazole 100 mg/kg SID PO for 3 days. The author has observed severe cases of trichomoniasis causing marked injury and destruction of vital structures of the middle and inner ear. These cases carry a poor prognosis.

Miscellaneous Medical **Disorders**

TOXICOSIS

Ammonium chloride toxicosis is a common medical disorder in falcons in the Middle East. At the end of the molting season, many falconers routinely administer ammonium chloride to their falcons. The theory behind this practice is belief that ammonium chloride dissolves the fatty layer accumulated in the stomach throughout the long molting season, resulting in a hungrier bird. Other falconers prefer to administer this substance only if a falcon failed to make a kill or showed little interest in a chase.

This toxic agent is usually administered to falcons in the form of a large crystal. Three to five minutes after administration, falcons vomit violently, bringing up large quantities of thick white to green-yellow mucus. However, often the large crystal breaks down into smaller fragments within the crop, resulting in only partial vomition of the crystal originally swallowed, an event that usually goes unnoticed by the falconer. Acute ammonium chloride toxicity can cause death within 10 to 15 minutes after administration. Rapid loss of appetite, progressive weight loss and the passing of characteristic dark metallic green mutes characterize chronic toxicosis. Terminal signs include incoordination, inability to stand, seizures and

Fig 40.77 | Lead toxicosis in a peregrine falcon. Common clinical signs of lead toxicosis include ataxia, hock sitting, hyperesthesia and convulsions. Falcons in the Middle East are commonly affected by ingesting lead pellets or lead fragments found in the carcasses of shot prey offered by falconers.

Fig 40.78 | A large lead pellet found in the gizzard of a saker falcon. The bird was presented in a state of collapse and displaying severe convulsions. The pellet was retrieved using a flexible endoscope.

opisthotonos, followed by death. The severity of clinical signs depends on the total amount of ammonium chloride ingested.94 Mild toxicosis cases respond well to fluid therapy and force-feeding for 3 to 5 days.

Falconers in North America and Europe have used "rangle" since medieval times to produce the same effect as that obtained using ammonium chloride by falconers in the Middle East. "Rangle" are small stones commonly found along river banks. Field biologists have observed many species of falcons and other birds of prey, in many different parts of the world, ingesting these stones as part of their normal behavior. The stones are commonly cast out the following day. This phenomenon also has been observed in captivity, and the provision of such stones within aviaries should be promoted.

Clinical lead toxicosis in raptors is characterized by ataxia, paresis or paralysis of the wings and legs, amaurosis and convulsions (Figs 40.77, 40.78). In addition, the author has consistently observed the presence of hyperesthesia in falcons affected by clinical lead toxicosis. Diagnosis of lead toxicosis is carried out by detecting the presence of lead pellets or lead fragments within the gastrointestinal tract through radiography and/or the measurement of lead levels in whole blood. The use of a novel diagnostic system^{hh} was recently published.⁸⁷ Lead pellets are normally removed either by gastric lavage or via endoscopy-assisted retrieval with rigid or flexible endoscopes and long grasping forceps. Lead fragments are normally removed through gastric lavage only (Figs 40.79-40.81). In falcons, the treatment recommended by the author is disodium calcium edetate" at the dose rate of 50 mg/kg administered undiluted BID IM. Retesting is carried out every 5 days until the lead level is lower than 20 μg/dl. Falcons have been treated for up to 23 days without observing any deleterious effect.87

Pesticide toxicosis is a general term used to encompass groups of chemicals used to eradicate unwanted and destructive animals and plants. These different chemicals can be classified under three main groups: herbicides, insecticides and rodenticides. In captivity, most cases of toxicosis are due to negligence or accident. Often the instructions provided by the manufacturer are not adequately followed or are ignored, and products are placed in direct or indirect contact with the birds or their food, water or living quarters. In the Middle East, the author has observed several cases of toxicosis in which falconers have sprayed falcons with products commonly used against mosquitoes, flies and cockroaches. In a recent case a saker falcon was presented with hyperesthesia, ataxia, paresis of wings and legs and anorexia. The bird in question was sprayed with a product containing prallethrin 0.055%, tetramethrin 0.216% and d-phenothrin 0.095%. The bird survived and made a successful recovery with supportive therapy including the administration of 20 ml/kg lactated Ringer's SC SID for 5 days, vitamin B₁ IM SID for 5 days, vitamin B complex IM and force-feeding via a stomach tube with a mixture of whole ground quail, chicken liver and a carbohydrate/electrolyte solution (see Table 40.15).

Pesticides have produced a significant negative impact on free-living raptor populations in different parts of the world. In some areas, whole populations of raptors have been decimated due to the indiscriminate use of pesticides via direct toxicosis, the production of thin-shelled eggs or breeding disorders. Most incidents are related to the use of pesticides to control unwanted insects such as grasshoppers, or rodents such as voles and rats, or birds such as the red-billed quelea (Quelea quelea). In general, raptors are the species most commonly affected in most geographical areas of the world by the widespread use of pesticides, as they occupy a prominent place at

Fig 40.79 | A radiograph showing lead dust and lead fragments in the gizzard of a saker falcon. Often, lead pellets strike a bone, producing small lead fragments. Shot prey always contains this potential health hazard and should not be offered to raptors.

Fig 40.81 | Small blunt-end tubes commonly used to feed neonate lambs are useful for flushing the ventriculus of small to medium-sized raptors. Note the large syringe (60 ml) attached to the tube. Warm water (32-35° C) is commonly used as the flushing solution. A total volume of 180 to 240 ml is often necessary to dislodge all lead particles.

Fig 40.80 | The recommended way to remove lead dust and lead fragments is by repeatedly flushing the gizzard. It is important to place an endotracheal tube in order to avoid inhalation pneumonia during the process.

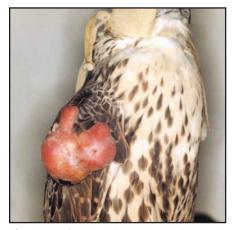

Fig 40.82 | A large lipoma near the shoulder joint of a saker falcon. This type of neoplasia is rare in raptors. The growth was successfully removed using standard surgical procedures.

the pinnacle of the food chain (see Chapter 31, Implications of Toxic Substances in Clinical Disorders).

NEOPLASIAS

A recent publication lists that 122 neoplasms of 39 types recorded from 120 birds were identified in 44 species of raptors.²⁰ The most common types found in the survey include fibrosarcomas (17 cases), adenocarcinomas (16 cases), squamous cell carcinomas (13 cases) and papillomas (6 cases). A thyroid adenocarcinoma in a bald eagle (Haliaeetus leucocephalus)6 and a thyroid cystadenocarcinoma in a saker falcon⁹⁰ have recently been described. These findings suggest that the incidence of neoplasms in captive raptors is not as rare as previously believed (Fig 40.82). More research is needed to determine the incidence of neoplasms in free-living raptors (see Chapter 20, Overview of Tumors).

UROPYGIAL GLAND IMPACTION

The uropygial gland, also known as preen or oil gland, is a bilobed gland located near the base of the tail. The gland secretes a lipoid sebaceous liquid, thick and transparent in appearance and with a characteristic light musky smell. The oil is spread on the plumage by the birds during preening to provide waterproofing. The secretion is carried by a number of ducts to an external papilla covered by a tuft of down feathers forming what is commonly known as the wick. One of the most common disorders affecting the uropygial gland is impaction. This is usually characterized by moderate to severe bilateral enlargement of the gland and a dry wick. Often the ducts of the wick are obstructed with hardened secretion forming a plug (Fig 40.83). The application of hot water compresses over the area and a gentle milking massage usually resolves the obstruction. More severe cases might require surgical intervention. In these cases,

two small incisions are made parallel to the wick, the contents are expressed and the area is irrigated with an antibiotic solution. Usually no suturing is required.

Molting Disorders

Molting is a natural process involving the periodic shedding and replacement of feathers within an annual cycle. In Falconiformes, the molt usually begins with the loss of primary feather No 4 progressing sequentially inward and outward from this point. Accipiters, harriers, Harris hawks, New World vultures and kites, however, follow a descending pattern similar to that of Passeriformes, in which the shortest innermost primary is shed first, proceeding sequentially toward the longer outermost feather. Large vultures and eagles tend to have a more erratic molting pattern, in which feathers from different locations are shed without following a particular order.²⁹

Raptors in captivity often suffer from molting disorders including delayed molt, sudden shedding of a large number of feathers from one particular area, twisted feathers, stress or fret bars, "pin" feather and "pinched" feathers (Fig 40.84). Molting disorders might be the result of ectoand endoparasitism, trauma, follicular infection or use of certain pharmacological agents during molting, but are most frequently the result of nutritional deficiencies. The need to provide a suitable environment, an appropriately diverse diet and adequate vitamin/mineral supplementation during the molting period cannot be overstated. (Ed. Note: If the proper diet is fed, supplementation can lead to toxicities).

Molting can be induced by confining raptors to secluded environmental chambers and gradually modifying the photoperiod, temperature and humidity. The molting process also can be induced and accelerated with 1 mg/kg levothyroxine sodium (thyroxine) SID PO until molt is initiated.5 Other authors have suggested doses of 25 µg SID PO for 1 week, followed by $50 \mu g$ SID for 1 week, then 75 μ g SID for 1 week, then 50 μ g SID for 1 week and finally 25 µg SID for 1 week for a red-tailed hawk (Buteo jamaicencis) weighing 1.4 kg.52 It has long been recognized in the ancient Arab literature that feeding sheep thyroid gland can induce molting in raptors. Caution has been expressed about how to satisfy the voracious appetite of raptors for the first few days after they have consumed approximately 25 g of beef thyroid gland. The use of thyroxine to induce and accelerate molting in raptors is prescribed only in selected cases of delayed molt (Fig 40.85). This therapy should be accompanied by an adequate and balanced diet and suitable housing conditions throughout the entire molting period.

Fig 40.83 | Falconers in the Middle East often use needles in an attempt to open obstructed ducting of the uropygial gland. Poor asepsis and inadequate procedure often leads to infection and necrosis.

Fig 40.84 | A saker falcon without the main flight feathers. The falcon was administered one of the numerous commercial products widely available in the Middle East to induce molting. The powder is believed to be desiccated thyroid gland.

Fig 40.85 | Feathers molted prematurely during growth and development. The presence of such feathers, commonly called "pinched feathers," is the result of follicular infection, nutritional deficiencies or high stress during the molting period.

Acknowledgments

The author extends thanks to HRH Prince Fahad bin Sultan bin Abdulaziz Al Saud for his support to the advancement of falcon medicine and to Mr. Basil Al Abbasi, Director General, for his continuing interest in the clinical and research program of the Falcon Specialist Hospital and Research Institute; to Shinto K. John for compiling the reference tables; to Generoso Quiambao for preparing the photographic material; and to Dr. Jesus Naldo for proofreading the manuscript and for providing useful comments.

Management of Captive

Ratites

BOB DONELEY, BVSc, FACVSc (Avian Health)

Fig 41.1 | North Island brown kiwi.

Although the demand for veterinary input into the ostrich and emu industries is not as great today as it was in the 1990s, veterinarians are still called on to give advice and to treat ratites of all descriptions. This chapter seeks to present new and updated information on these flightless birds as well as refer the reader to references where more comprehensive information may be found.

Classification

Ratites are not an order or family of birds. Rather, they are a group of birds sharing similar physical characteristics. They are all flightless birds, with elongated necks and relatively long legs adapted for walking and running (Fig 41.1, Table 41.1). The name ratite comes from the Latin *ratis*, or raft. This refers to the flattened, raft-like sternum that lacks a keel and ventral musculature — an adaptation to their loss of flight. Ratites are naturally found on three continents (Africa, Australia and South America) and two islands (New Guinea and New Zealand), all in the Southern Hemisphere. Nevertheless, commercial development of the ostrich and emu industry is seen on every continent except Antarctica.

Table 41.1 | Classification of Ratites.

There are 11 species of birds grouped as ratites. They come from four orders and five families.

Common Name	Order	Family	Species	Subspecies
Ostrich	Struthioniformes	Struthionidae	Struthio camelus	S.c. camelus (North African) S.c. molybdophanes (Somali) S.c. massaicus (Massai) S.c. australis (South African)
Ети	Casuariiformes	Dromaiidae	Dromiceius novaehollandiae	_
Southern/double-wattled cassowary	Casuariiformes	Casuariidae	Casuarius casuarius	_
Bennett's/little cassowary	Casuariiformes	Casuariidae	C. bennetti	_
Northern/single-wattled cassowary	Casuariiformes	Casuariidae	C. unappendiculatus	_
Greater rhea	Rheiformes	Rheidae	Rhea americana	_
Darwin or lesser rhea	Rheiformes	Rheidae	R. pennata (formerly Pterocnemia pennata)	_
Tokoeka kiwi	Apterygiformes	Apterygidae	Apteryx australis	_
Brown kiwi	Apterygiformes	Apterygidae	A. mantelli	_
Little spotted kiwi	Apterygiformes	Apterygidae	A. oweni	_
Great spotted kiwi	Apterygiformes	Apterygidae	A. haasti	_
Rowi kiwi	Apterygiformes	Apterygidae	A. rowi	_

Some classifications place the tinamous (Order Tinamiformes; Family Tinamidae), a South American partridge-like bird, in the ratite group. They share some physical characteristics with the ratite groups described above, especially the rhea.

Clinical Anatomy and Physiology

Ratite anatomy and physiology are similar to other avian species, particularly poultry and psittacines, although there are some clinically significant differences. 3,31,34,63

INTEGUMENT

The skin of ratites is thicker than that of many other avian species; consequently, ostrich and emu hides are in demand by the leather industry. Rough handling easily damages the skin, and scarring or bruising detracts from the hide's value. Care must be taken when handling these birds to avoid such damage. Kiwi skin is particularly thick and includes a prominent hypodermis for fat storage (Fig 41.2). Sternal callosities (dermal thickening for weight bearing when in sternal recumbency) often are present over the sternum of ostriches, emus and rheas. A similar condition also frequently is present over the ventral-cranial portion of the pubic bone in the ostrich. The plantar surface of the foot has a dermal pad of packed vertical rods of cornified tissue, with underlying paired, tubular fat bodies for additional padding.

The toenails are blunted in ostriches, but are sharper in other species, especially cassowaries, which can have 12-cm spikes on the medial toes. Prior to the breeding season, male North Island brown kiwis can store as much as 50% of their body mass as subcutaneous and intracoelomic fat. The feathers of ratites lack the barbules seen in other species, and so the feather vane does not interlock tightly. This gives ratite feathers a unique hairlike appearance, but also makes them less water-resistant. Contrary to earlier work, the presence of filoplumes has been reported in ostriches.⁶ These slender feathers

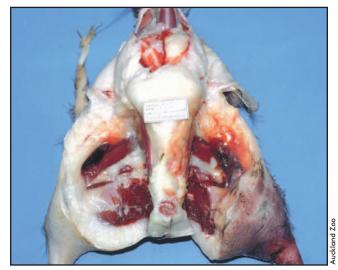

Fig 41.2 | Dissection showing massive deposits of subcutaneous and intracoelomic fat in a male North Island brown kiwi early in the breeding season (September). Ironically, the bird died after being caught in a leg-hold trap set for its mammalian predators.

arise from small follicles alongside the larger follicles of contour feathers. The presence of a large number of filoplumes (and therefore their follicles) can detract from the value of a hide. There may be a genetic factor for these filoplumes, and their presence should be considered a selection criterion for breeding birds.⁶

Thermoregulation in ostriches is achieved by evaporative cooling from the respiratory tract and convection heat loss through the skin. The thighs of the ostrich, normally covered by the wings, are bare of feathers. Contour feathers on the body can be erected or flattened voluntarily. A heat-stressed ostrich will hold its wings away from the body and erect its contour feathers, thus maximizing heat loss from the body (Fig 41.3). Conversely, in

Fig 41.3 | Heat stress in an ostrich chick. Note the raised feathers and the wings held away from the body, thus maximizing heat loss. In these conditions, appetite can be reduced by as much as 40%, with resultant stunting and mortality.

Fig 41.4 | North Island brown kiwi chick showing vestigial wing and axillary apteria (featherless skin), which is the site used to implant subcutaneous identity microchips.

cold weather, the ostrich will flatten its feathers and wings against the body, conserving body heat. It may also lie down on its sternum, further reducing the area of skin available for convective heat loss.

MUSCULOSKELETAL SYSTEM

With the loss of flight, ratites have lost the need for pneumatized bones. Consequently, with the exception of a pneumatized femur in the ostrich and emu, ratite bones are heavier and denser than those of other avian species. In the ostrich, the thoracic girdle (coracoid, clavicle and scapula) has fused, a further adaptation to the loss of flight. Ostriches and rheas have relatively large wings, while the wings of other ratites are comparatively much smaller (Fig 41.4). Ostriches have two toes (digits 3 and 4), the rest have three (digits 2, 3 and 4) all forward, and all toes have four phalanges on each digit.

In the ostrich, emu and rhea, the muscles of economic importance are found on the pelvic limb and along the lumbar vertebrae. This makes these muscles unsuitable for intramuscular injections, as abscesses or scar formation could lead to downgrading or condemnation of the carcass. In all ratites, the reliance on the legs for locomotion means that particular care must be taken that intramuscular injections do not result in pain and lameness. The lack of pectoral muscles on the ventral sternum leaves the muscles alongside the thoracic vertebrae as the area most suitable for injections. Note that care must be taken to minimize hide damage through repeated injections.

DIGESTIVE SYSTEM

Ratites are primarily herbivorous (although cassowaries are known to eat small mammals), and their digestive tracts are basically similar to those of other herbivorous

birds.³¹ The exception is the kiwi, which is primarily insectivorous.¹⁸ Its anatomic and physiologic differences reflect the evolutionary influences of the forages available in their natural habitat.

The esophagus lies on the right side of the neck. It contains numerous longitudinal rugae that allow expansion when a bolus of food is swallowed. The ostrich cock, when displaying territorial behavior or seeking to attract a mate, inflates the esophagus with air and then expels it with a loud "boom". There is no crop in any of the ratites, and the esophagus opens directly into the proventriculus. There is no esophageal/proventricular sphincter; therefore, regurgitation of proventricular contents can be of concern during anesthesia.

In the ostrich, the large, thin-walled proventriculus lies caudal to the ventriculus. In other ratites, the proventriculus is cranial to the ventriculus. The proventriculus of the rhea is small, while those of the kiwi, emu and cassowary are intermediate to those of the ostrich and the rhea. The ventriculus in the ostrich is separated from the proventriculus by a large opening that facilitates the surgical removal of ventricular foreign bodies via a proventriculotomy.

Ratites lack cellulase needed to digest plant fiber and therefore rely on fermentation of the fiber in the intestinal tract. This fermentation requires a slow rate of passage through the tract and an area where microbes can colonize without being swept away. ¹⁶ This is where major anatomic differences exist among ratites.

Ostriches and rheas have a comparatively longer rectum and larger ceca than the emu and cassowary, perhaps indicating their development as hindgut fermenters of relatively poor-quality fodder. The ventriculus of the cassowary lacks a koilin lining. The emu and cassowary,

Fig 41.5 | Dissected normal gastrointestinal tract from a kiwi showing paired ceca.

Table 41.2 | Gastrointestinal **Transit Times in Ratites**

Species	Transit time
Ostrich (immature)	36 hours
Ostrich (mature)	48 hours
Ети	5-6 hours
Cassowary	_
Rhea	_
Kiwi	5-20 hours

evolving on a comparatively higher quality diet, have much longer small intestines, but small, non-functional ceca and a relatively shorter rectum. Overall, the intestinal tracts of the emu and cassowary are relatively shorter than those of the rhea and ostrich. The kiwi has long, paired ceca and a very short rectum (Fig 41.5). There is no gall bladder in the ostrich or emu, while the cassowary has one. Gut transit times vary with age and species (Table 41.2). For example, the emu has the capability of retaining larger fibrous particles in the ileum, allowing for greater fermentation.

RESPIRATORY SYSTEM

Despite their adaptations to a terrestrial lifestyle, ratites have retained a respiratory tract similar in structure and function to that of other avian species. Unlike other birds, however, the sternum of the ratite does not move during respiration. It is fixed to enable it to support the weight of the bird when resting. Respiration, therefore, relies on the lateral movement of the ribs, a fact that should be considered during anesthesia and recovery.63

Like other avian species, the tracheal rings of most ratites are complete cartilaginous rings. The exception is the emu, where a longitudinal cleft 6 to 8 cm long is found on the ventral surface of the trachea 10 to 15 cm cranial to the thoracic inlet. A membrane covers this

cleft. As the emu matures, the cleft develops into an expandable pouch, which can be inflated to produce a booming noise in hens and a growling noise in cocks.31 This can be a complication during anesthesia if positive pressure ventilation is used, as gases may be directed into this pouch and away from the respiratory system. This can be overcome by wrapping the base of the neck with a non-adhesive bandage during anesthesia. 31,63

The syrinx in ratites is poorly developed compared to other birds, a reflection on their lack of vocalization. Although the anatomy of the air sacs is similar to that of other birds, their capacity is much reduced.63

The respiratory rate varies according to age and ambient temperature. Ostrich chicks have respiratory rates of 12 to 60 breaths per minute, compared to the adult resting rate of 6 to 12 per minute. In hot conditions, this adult rate can increase to 40 to 60 breaths per minute.31,34

REPRODUCTIVE SYSTEM

Like other birds, most ratite hens develop only the left ovary and oviduct. The exception is the kiwi, which has two functional ovaries and oviducts. 14 The oviduct(s) open into the urodeum. In the ostrich, it is possible to pass a guarded culture swab into the first few centimeters of the caudal oviduct through this opening from the urodeum. This opening can be found within a small mound on the left side of the urodeum, in the 10 o'clock position. On the ventral floor of the proctodeum is a small genital mound. In the ostrich, a small (1 to 3 cm) phallic-like structure arises from this mound. An even smaller structure is present in the emu, but only the mound itself is present in the cassowary and rhea.

Ratite cocks have a phallus. This differs from the mammalian penis in that there is no urethra within it, and it plays no role in urination. Ostrich and kiwi phalluses are solid structures, unlike those of the emu, cassowary and rhea, whose phalluses are spiral-shaped with a cavity and a partially inverted sleeve that everts during erection. This gives the appearance of a urethra, but it is a blind-ended structure.31 In all ratites, the non-erect phallus is found on the floor of the proctodeum. During erection, the phallus becomes engorged and is everted from the cloaca. Semen is directed along a dorsal phallic sulcus into the hen's cloaca.

The sex of ratites can usually be determined by palpation or examination of the cloaca (Table 41.3). In small chicks, the cloaca can be everted by digital pressure and visually examined. In older chicks and adults, one or more fingers can be inserted into the proctodeum and the ventral floor palpated to detect the presence or absence of a phallus (Fig 41.6). It must be noted that in

Table 41.3 | Sex Differentiation of Ratites³¹

In the much smaller kiwi, cloacal palpation is difficult, and the length of the bill and tarsus (both being longer in the larger female) generally determines sex. This difference becomes evident at approximately 6 months of age.

Species	Juvenile, Male	Juvenile, Female	Adult, Male	Adult, Female
Ostrich	Phallus round in cross section, 1-4 cm long, dorsal sulcus	Phallic-like structure flattened in cross section, 0.5-1.0 cm long, no sulcus	Phallus 20-40 cm, curved	Phallic-like structure small, 1-4 cm long, straight
Emu	Hollow tube 0.5-1.0 cm, spirals as bird gets older	Genital mound, slight prominence on genital mound	Spiralled phallus, hollow tube, 3-12 cm long	Genital mound, slight prominence on genital mound
Rhea	Similar to emu, but more elongated	Genital mound with no prominence	Similar to emu	Genital mound with no prominence
Cassowary	Phallus 0.5-1.0 cm, triangular in cross-section	Small genital mound	Triangular-shaped phallus pointed caudally	Genital mound
Kiwi	_	_	Triangular-shaped phallus pointed caudally	_

Fig 41.6 | Cloacal sexing in an ostrich to detect the presence of a phallus.

some individual juveniles, this method is inaccurate because of variations in phallic size, and the clinician must be prepared to repeat the procedure when the bird is older. Visually sexing a ratite by its size or plumage color, while often accurate, can be misleading. In the ostrich, for example, a lack of estrogen gives the cock bird its striking black plumage. However, some infertile hens have a similar lack of estrogen and have the same black plumage as cocks. These so-called "black hens" have been the subject of several lawsuits when sold as cocks without cloacal palpation to confirm sex.

The ratite cock has paired intra-abdominal testes that increase dramatically in size with the onset of the breeding season (Table 41.4). Outside of this breeding season, the testes return to their quiescent size and semen production ceases. Semen collection for assessment of fertility is unsuccessful at this time and should not be attempted.²⁶

Ratites are seasonal breeders, although some individuals will breed year round. Ostriches, kiwis and rheas start to breed as day length increases, while emus breed as the day length starts to shorten. Cassowaries breed in late winter-early spring, coinciding with the peak availability of fruit in their natural habitat. Ostrich hens often will start

Table 41.4 | Sexual Maturity in Ratites

The age of onset of sexual maturity varies among species, sex, and differing nutritional planes and management systems.

Species	Age of Sexual Maturity
Ostrich	24-36 months
Emu	20-24 months
Rhea	18-24 months
Cassowary	42-48 months
Kiwi	42-54 months

to lay before the cock has come into peak sexual activity, so the first few eggs in each season often are infertile.

URINARY SYSTEM

Ratites have a urinary system similar to that of other birds and, like other birds, produce copious amounts of dilute urine that is resorbed and concentrated in the cloaca and caudal rectum. Ostriches are capable of expelling urine without defecating, unlike most other birds. They are unable to urinate except when standing, and an ostrich that has been recumbent for some time will have a cloaca distended with urine.³⁴

Nutrition

In the last few years, the interest in farming some of the ratites has dramatically increased our knowledge of their nutritional requirements. However, research into this area is far from complete, and new information and concepts are becoming known each year. 1.8,15,16,18,34,47 Key areas to consider in ratite nutrition are as follows:

- The adaptation to a terrestrial life-style has resulted in nutritional requirements very different from those of flighted birds.
- There are significant differences among ratites in anatomy and physiology and consequently their nutritional requirements.

Fig 41.7 | Free-ranging emus in Australia.

- There are significant differences between juvenile and adult ratites (of the same species) in anatomy and physiology and consequently their nutritional requirements.
- There are economic aspects of feeding farmed ratites that must be considered when formulating diets.

The terrestrial lifestyle of ratites does not require the easily digested and rapidly utilized high-energy diets needed by flighted birds. Many ratites in their natural habitat live in semi-arid environments, grazing on bulky, high-fiber, low-quality roughage. Lacking cellulase to digest this fiber, ratites have to rely on fermentation of the fiber in their relatively long intestinal tracts to obtain the full benefit of their diet. Emus (Fig 41.7), with comparatively shorter intestinal tracts and vestigial cecum, are able to selectively retain larger fiber particles in the distal ileum allowing fermentation.¹

A notable exception is the cassowary (Fig 41.8), living in rain forests and sclerophyll forests of New Guinea and North Queensland, which is primarily frugivorous (fruit eating) although other plants and even small animals are readily eaten. The kiwi feeds in leaf litter, eating 40 to 45% small invertebrates, 40 to 45% earthworms and 10 to 15% plant material.¹⁸

Juvenile ratites differ markedly from the adults. In the first week of life, the abdomen is dominated by the presence of the large yolk sac. Juvenile ratites, in their first few weeks of life, are nutritionally dependent on the quality of the parental diet and its effect on the yolk composition. The yolk provides fat, fat-soluble vitamins and some protein, and the yolk sac gradually reduces in size as the yolk is utilized. At the same time, the gastrointestinal tract increases in size. By 2 to 3 weeks of age, the yolk sac is usually completely resorbed, and the abdominal viscera are dominated by the proventriculus,

Fig 41.8 | The cassowary is primarily frugivorous.

cecum and large intestine. Fiber digestibility parallels this same trend. In the ostrich, for example, fiber digestibility at 3 weeks of age is only 6%, increasing to 58% by 17 weeks. Fat digestibility also increases in a similar fashion, except that the 3-week-old chick has a fat digestibility of approximately 44%. 1.28

With the development of the ratite industry as a commercial enterprise (with meat, oil and leather as its products), economic factors become pivotal in diet selection with the desire to reach a good slaughter weight at an early age. In much of South Africa, for example, ostriches are traditionally slaughtered at 14 months of age. This situation is rapidly changing toward younger age processing. There are some types of ostriches that can attain body weights in excess of 95 kg as early as 7 to 8 months of age (Black, personal communication). However, the economic benefits of being able to slaughter birds months earlier than previously attained must be offset against the disadvantages of this rapid weight gain, namely angular limb deformities and other growth abnormalities.

Ratite nutrition, therefore, requires the development of diets for each species, as well as each life stage.¹

PRACTICAL FEEDING

Diets for the two main commercial species, the ostrich and emu, have been researched in some detail, but specific information on the other species is lacking. Prestarter and starter diets should be fed ad libitum (Tables 41.5, 41.6). Older birds should be fed 1.0 to 1.5 kg of a formulated diet per day. As the bird matures, the amount of good-quality fiber can be increased and the amount of formulated diet reduced. At 4 to 6 months, fiber should be no more than 33% of the diet; this can be increased to up to 60% in birds weighing more than 95 kg. The weight gains of birds on these diets, while slightly less than that of birds on 100% formulated diet,

Table 41.5 | Diet Recommendations for Emus^{1,8,34,47}

Diet	Age (months)	Est. Body Weight (kg)	Crude Protein (%)	Calcium (%)	Fiber (%)	Comments
Starter	0-1	0.5-1.3	17-25	1.1	>4	Feed ad lib.
Grower	1-16	2-40	16.5-23.0	0.9	>4	Can be used as a maintenance diet (see below).
Market	_	_	14	0.7	>4	Higher energy diet fed in the 2-3 months prior to slaughter in order to maximize fat deposition.
Breeder	20-24	40-45	15-25	2.1 (Females only)	>4	Feed 1.0-1.5 kg/bird per day. Intake drops by 30-50% with onset of the breeding season and increases again at the end of the season. This diet is nutrient dense and is fed ad lib from 1 month prior to breeding till 1 month after egg laying ceases.
Maintenance	16+	40-45	12-20	0.9	*	Intake varies with day length, peaking 1-2 months before maximum day length and then dropping as day length decreases.

^{*6%} at 3 weeks then up to $\leq\!60\%$ at 17 weeks on

Table 41.6 | Diet Recommendations for Ostriches¹

Diet	Age (months)	Est. Body Weight (kg)	Crude Protein (%)	Calcium (%)	Fiber (%)
Pre-starter	0-2	0.8-10.5	25	1.2-1.5	_
Starter	2-4	11-28	21.5	1.2-1.5	>4

Breeder ♀	Laying	_	14	2.0-2.5	8-60

are not significantly less. This feeding regime can result in a cost savings of up to 80%. 16

Emus and Ostriches

See Tables 41.5, 41.6 for practical feeding recommendations for ostriches and emus.

Rheas

Given the anatomic similarities of the digestive tracts of ostriches and rheas, it is reasonable to assume that their nutritional requirements are similar. A survey of freeranging greater rheas in Argentina showed that cultivated pasture, especially alfalfa, made up 39 to 63% of the diet. Grasses and rye made up the bulk of the balance, with seed and small invertebrates making up only a small portion. 46

Cassowaries

The short length of the cassowary's intestinal tract and its subsequent rapid gastrointestinal transit time means that cassowaries require a large volume of food—up to 10% of their body weight daily. Most zoos and wildlife parks feed each bird 4 to 5 kg of fruit daily, including tomatoes, bananas, apples, papayas, pears, watermelon, grapes, mangoes, plums, nectarines, cherries, kiwi fruit, figs, cantaloupe, eggplant, sweet potatoes and carrots. This often is supplemented with animal protein (day-old chicks, mice, rats), vitamins and minerals. Chicks are fed a similar diet in smaller proportions. A commercial diet is available in the USA for carnivores.

Kiwis

The Auckland Zoo in New Zealand feeds its captive kiwis a diet consisting of lean ox heart, diced fruit and vegetables, yeast, wheat germ, sunflower oil, calcium carbonate and a vitamin-mineral premix. This is supplemented with earthworms and invertebrates contained in provided leaf litter.³⁹ Captive kiwi chicks are introduced to worms and other invertebrates from 10 days of age and then rapidly convert to the artificial diet.

Behavior

An understanding of behavior in free-ranging and captive ratites is necessary to decrease stress and maximize production in both farmed birds and zoological specimens. Research has primarily focused on the ostrich.

There are four major behavioral areas of clinical interest: social behavior, feeding behavior, courtship and breeding behavior, and behavior of chicks.

SOCIAL BEHAVIOR

In their natural state and out of the breeding season, ostriches are gregarious animals, coming together in large flocks of varying ages and sexes, particularly around water holes. Within these flocks, however, there does appear to be a family social structure, with each group headed by a dominant male. During the breeding season these large flocks dissipate, with pairs and single birds being commonly seen. Free-ranging ostriches rarely associate or interact with other species, preferring to ignore them.²³

In captivity, ostriches are generally run together as pairs and trios. Interaction between other ostriches seems to be mainly confined to males pacing the fence alongside each other in a territorial display. Occasionally this behavior can be detrimental to reproductive success, as males spend more time confronting each other than they do mating. However, colony breeding of ostriches is not uncommon, and confrontation does not appear to

be a hindrance to production.

Rheas are not nomadic birds, as they are rarely subjected to the effects of drought. One cock and several hens will reside in a family territory during the breeding season, with other cocks vigorously expelled. However, these territorial disputes disappear outside the breeding season, and flocks of up to 50 birds may form.⁴⁰

Ostriches, emus and rheas in general show little aggression toward each other outside their breeding season.⁴⁰

Cassowaries, on the other hand, tend to be loners, living a solitary existence within an apparently defined territory. When meeting another cassowary or another animal, cassowaries react aggressively, stretching their bodies and rumbling lowly. If this fails to dissuade the intruder, an aggressive attack may follow. For this reason, they should not be housed with other species, and humans bushwalking in their natural territory need to be cautious, particularly during the breeding season.⁵⁵

With the exception of the Stewart Island brown kiwi, where juveniles stay with their parents in a social group for at least their first year, kiwis also are highly territorial, solitary birds.49

FEEDING BEHAVIOR

Time-activity budget studies of wild ostriches indicate that they spend approximately 33% of the daylight hours feeding. The amount of time spent feeding was affected by flock size and sex. In smaller flocks more time was spent in vigilant behaviors, watching for predators and rivals. Males spent more time being vigilant than females. As flock size increased, females spent more time feeding while males decreased their feeding time. It is thought that this may be due to increased rivalry among males in larger flocks. This behavior is replicated in captive birds.²³ Captive females appear to have longer feeding bouts due to their higher energy demands associated with egg production. Males, on the other hand, feed for shorter periods due to competitiveness with other males.56

Ostriches prefer to eat natural vegetation, apparently preferring it to a formulated diet. Green annual grasses and forbs are preferred, although leaves, flowers and fruit also are consumed. Ostriches also eat stones, presumably to aid in the grinding and digestion of food. Abnormal feeding behaviors, such as the consumption of dirt and branches, are thought to be due to stress.23,34

Emus prefer high-quality foodstuffs, grazing on green plant materials, seed heads, ripening fruit, berries and insects.⁴⁷ This higher quality diet may be a reflection of their shorter digestive tract and decreased gut transit times, 5 to 6 hours as opposed to 48 hours in ostrich.

Cassowaries feed predominantly on fallen fruit, but will eat almost anything, including dead rats, birds, small reptiles and fungi. As frugivores, they play an important role in the rain forest ecology, spreading undigested seeds throughout their territory. It is recorded that 21 species of rain forest plants require passage through the cassowary's digestive tract to germinate. A cock bird rearing chicks will pick up a food item and drop it in front of the chicks, clapping his beak to draw their attention to the object.55

Kiwis are unique among ratites in being strictly nocturnal and having a highly developed sense of smell. The slit-like paired nostrils are situated at the distal tip of the bill and are driven into the soil and leaf litter in search of a wide range of invertebrate prey. These include caterpillars and pupae of moths, larvae and adult beetles (especially chafer beetles), wood lice (slaters), centipedes, millipedes, slugs, snails, cicada nymphs, crickets, wetas, ants and spiders. 49 Berries and seeds of native plants such as hinau (Elaeocarpus dentatus) and miro (Prumnopitys ferruginea) also form a small but significant part of the diet.49

COURTSHIP AND BREEDING **BEHAVIOR**

Ostriches

Ostriches breed in a defined breeding season, usually during the spring and summer months. Hens will usually display courtship behavior before the cocks and may even lay the first few eggs before being mated. The hen displays in front of an appropriate mate, lowering her head and spreading and fluttering her wings (Fig 41.9). She opens and closes her beak rapidly, making a soft noise as she does so.

Male courtship behavior begins more slowly. He develops a deep red coloration of the beak and featherless skin over the tarsometatarsal area. In some species, the skin of the neck and thighs also develops a red blush. Aggression toward other males increases, and the erect phallus is prolapsed from the cloaca and displayed. Territorial and display behavior such as booming and kantelling increase. The cock drops to his hocks, spreads his wings and swings his head from side to side, striking his back at the end of each swing.

When both birds are ready to mate, the hen will sit down and extend her head and neck along the ground. The cock approaches and sits astride her, just off to the right. The phallus enters the hen's cloaca and mating proceeds with some kantelling behavior displayed. Mating takes approximately 1 minute.

The free-ranging ostrich has a communal nesting system,

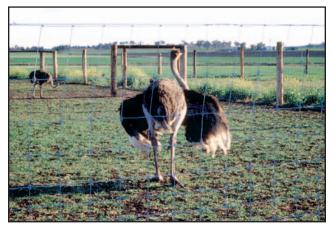

Fig 41.9 | A mature ostrich hen shows reproductive behavior by opening her wings and making a soft "cluck".

usually utilized by one cock, one "major" hen, and two "minor" hens. 40 The cock digs a number of shallow scrapes, one of which is chosen by the major hen. Egg laying proceeds in this nest, but the other minor hens may lay in the same nest. The major hen lays approximately 11 eggs; the minor hens may contribute another 15 to 25 eggs. Egg laying occurs in the late afternoon and early evening, during which time both cock and hen attend the nest. The clutch size builds up over a period of up to 30 days, but incubation does not begin until the clutch is complete. Once the major hen starts to incubate, she will selectively remove many of the eggs of the minor hens from the center of the nest, pushing them to the periphery of the nest where they do not develop. 23

Emus

Emus also are seasonal breeders, laying their eggs in late autumn and winter.⁷¹ Emu hens are dominant to the cock and make a drumming noise during the breeding season. The male responds with a growling noise. Emu males are primarily monogamous, with one cock pairing with a hen for the breeding season.⁴⁴ When ready to mate, the hen drops to the ground, extending her cloaca. The cock drops to his hocks behind her and intromission occurs. The cock picks the back of the hen's neck during mating.³³

Emu hens start their laying by depositing eggs randomly around a pen. When a nest site is chosen, the remaining eggs are laid there and the dispersed eggs are collected by the cock and relocated to the nest site. After 6 to 10 eggs have been laid, the cock will start to incubate the eggs. Although further eggs laid near him are rolled under to join the others, in many cases the hen will stop laying or move on to find another non-incubating mate. ⁵⁹ At this stage the cock will hardly move, standing only to turn the eggs. His body weight will significantly decrease — a limiting effect on production. ⁷¹

Rheas

Rhea cocks also incubate the eggs, but a hen may seek out more than one mate. Cocks will defend their territory and nest from other males through physical aggression such as shoving and beak grasping. Once the cock has established his territory, he attracts hens with his courtship displays and behavior. He prepares a shallow depression in the ground as a nest, into which multiple hens will lay. Females lay every 2 to 3 days until the nest contains approximately 13 to 30 eggs, at which point the cock will not allow the hens' access to the nest. The eggs are incubated for approximately 35 to 40 days, with the chicks hatching synchronously over 24 to 28 hours.

Cassowaries

Cassowaries breed in late winter/early spring coinciding with the peak availability of fruit. As the breeding season approaches, the hen becomes more tolerant of cocks and eventually breeding pairs form. A pair remains together for several weeks until the hen is ready to lay in a shallow scrape in the rain forest floor. The male displays to the hen by "dancing" around her, inflating his esophagus and emitting a series of low booming noises. The hen reciprocates by standing with her neck upright and her head tucked down, emitting a low rumble while vibrating her neck. When she is ready to mate, the hen sits down; the cock approaches and, if the hen does not move away, he pecks at her neck, squats and mates from behind. The whole process takes 30 minutes.55 Once the eggs are laid, the hen leaves and takes no further interest in them. She may seek out another cock and repeat the whole ritual. Up to 8 eggs may be laid in a single clutch, although it is rare that this many hatch and survive.55

Kiwis

Kiwis live in stable pairs within a territory that may be aggressively protected. They lay only two eggs, one from each ovary, usually 24 days apart. They are usually laid in a burrow and are incubated by the male. (The exception is the Stewart Island brown kiwi, where the female does assist incubating the eggs, possibly due to the colder weather). Eggs are laid between July and February, and lost clutches are not immediately replaced. The male emerges from the burrow each night for a few hours to feed until within a few days of the eggs' hatching. During the incubation period (70-90 days), the male can lose up to 17% of his body weight.

BEHAVIOR OF CHICKS

In the natural state, hatching of ostrich eggs takes place over 2 to 3 days, during which time the chicks remain "brooded" by an adult. When all have hatched, the chicks form crèches of up to 30 individuals, overseen by

Fig 41.10 | Ostrich chicks feeding. Note the colored mat, which attracts the chicks' attention.

a single pair of adults. These crèches often will merge when they meet, although older chicks are not usually accepted into younger groups. When the chicks are approximately 1 year old, they are left by their guardians in compact peer groups to fend for themselves.²³

Ostrich chicks are naturally gregarious and do not do well if reared in solitude.23 Lacking parental security and the comfort of their crèche, isolated chicks (both freeranging and captive-bred) will suffer severe stress and anxiety.34 Captive-bred chicks imprint on their human caretakers and look to them for parental security. If the caretaker leaves, the chicks become stressed, leading to decreased food intake, gastric stasis and eventual death. This can be overcome by setting a routine for the chicks in their first 6 weeks (better enabling them to deal with stressful situations), and by having a caretaker with the chicks as much as possible.42

A time/activity budget study of captive ostrich chick behavior showed that chicks aged 7 to 14 days spent equivalent amounts of time feeding from the floor and walking around their enclosure (27.7% and 23.1%, respectively).23 Lacking an adequate thermoregulatory capacity, chicks must spend some time under a brooder lamp warming themselves (11.2%). Presumably, freeranging chicks would fulfill this requirement by brooding under an adult guardian. The balance of their day was spent pecking at objects (10.2%), standing (6.7%), drinking (5.8%) and feeding from a tray (3.5%).

This study would indicate that feeding chicks from a tray or dish is less successful than placing the food directly on the ground (Fig 41.10). As 10% of their time was spent pecking at other objects, it would appear that pecking is a means for ostriches to locate food. As they learn by mimicry, this behavior spreads rapidly through a group of chicks. Another study indicated that chicks prefer the colors green and white, pecking at these colors in preference to other colors.24

Aberrant behaviors, such as pecking at non-food items and other chicks, can become highly repetitive and habitual. Pecking at other chicks may be an aggressive behavior but is more likely to be misdirected feeding behavior or a response to stress. Once this behavior becomes habitual, it is difficult to stop. Chicks that peck the most have the slowest growth rates and may even die.23

Emus

Emu chicks spend their first week primarily huddled under a heat source. Any activity is done as a group and is usually initiated by older chicks. Feeding as a group is of short duration; as an individual, it is even shorter. As the chicks get older, they become more active, spending more time running, chasing, pecking at objects and feeding. Sudden disturbances will induce clustering behavior, all the chicks coming together in a huddle. Emu chicks, like ostriches, learn by mimicry, usually by watching the behavior of older chicks.30

Rheas

Rheas also rear their chicks in crèches, overseen by a single male. Newly hatched chicks are readily adopted into these crèches with good survivability of the new chicks. Smaller chicks adopted into groups of larger chicks have a higher mortality.⁴¹ The precocial chicks, gray with darker stripes, will stay with the male for approximately 6 months, often taking shelter under the wings of the male when he lies down. Juvenile birds may stay together for several years until reaching sexual maturity (Smith, personal communication).

Cassowaries

Cassowary cocks look after their chicks until they are about 9 months old, although chicks of 16 months have been seen accompanying the cock. When the chicks are approaching maturity, the cock chases them away and they establish their own territories.55

Kiwis

The kiwi hen, while not sharing the incubation with the cock, remains nearby and spends time with the male and chicks once they are hatched. Chicks are precocial and independent within approximately 14 to 20 days, but remain with or near their parents for up to several years. With the exception of the Stewart Island brown kiwi, kiwi chicks are fully independent after their first 3 weeks of life.49

Production Management

With the advent of commercial farming of some ratites species and improved captive breeding of others in

zoological parks, the management of these birds has received much attention in recent years. Decreased production and most disease problems in ratites often can be traced directly to management faults and errors. An understanding of the management principles of ratite production is, therefore, essential when assessing problems with these birds.

With the modernization of the ostrich industry, more research on management of this species has been done than for any other ratite. Unless otherwise stated, the following information refers to ostriches. Care must be taken in extrapolating this to other ratites.

EGGS

Incubation

Artificial incubation of eggs is widely practiced in all ratite species in an endeavor to increase production. Egg characteristics and incubation requirements for ratite species are contained in Table 41.7.

Given healthy, fertile eggs, there are nine parameters for successful artificial incubation: selection of eggs for incubation, egg collection and sanitation, egg storage, incubator temperature, relative humidity, ventilation, turning and positioning of eggs, hygiene and monitoring and record keeping.

Selection of Eggs for Incubation

In the early days of the recent ostrich "boom," every egg was worth a lot of money, and eggs that should not have been incubated were set. The lesson learned was that these eggs rarely hatched, or, if they did, they produced weak chicks. Not only was the labor intensity in maintaining these eggs and chicks not comparable to the results obtained, but they also acted as "disease multipliers", adding greatly to farm problems.

Undersized eggs or those with poor shell quality have a tendency to lose excessive moisture content during incubation, producing weak, dehydrated chicks. Conversely, oversized eggs or those with excessively thick shells do not lose enough moisture, and the resultant chicks are edematous and weak. Neither type of chick survives well.

It is therefore not advisable to set eggs that are heavily contaminated, cracked, undersized (eg, ostrich eggs less than 900 g), oversized (eg, ostrich eggs greater than 1500 g) or that have poor shell quality (eg, too thick or too thin).

Egg Collection and Sanitation

Microbial contamination of eggs can be responsible for significant losses of fertile eggs, with infection rates

Table 41.7 | Egg Characteristics and Incubation Requirements of Ratite Species^{62,66}

	Ostrich	Emu	Rhea	Cassowary	Kiwi
Eggs per year	40-60	20-40	40-60	3-10	1-6
Egg weight (g)	900-1700	500-700	400-700	500-700	400-450
Incubation period (days)	41-43	48-50	36-41	47-54	70-90
Temperature (° C)	36.0-36.4	35.2-35.5	36.0-37.2	36.1-36.7	35.5-36.5
Relative humidity (%)	22-36	35-50	55-70	55-70	60-65

Kiwi data from Auckland Zoo (unpublished)

ranging from 13.4 to 67% of dead-in-shell ostrich eggs. Most isolates are of fecal or soil origin.²² Clearly, success rates can be improved if this contamination is minimized or avoided.

Ratites should be provided with clean, dry, well-drained nest sites. Many birds will accept an artificial nest site, so care should be taken to locate it in an easily accessible area that meets the previous requirements. Wherever possible, eggs should be collected several times daily, with the last collection just before sunset. This regime will minimize the contact time the egg has with possible contaminants, which may be drawn through the shell as the egg cools.

Sanitation of eggs remains controversial, but obvious gross contamination should be removed with a soft, dry brush. The decision on whether to then wash the eggs, fumigate them or irradiate them with ultraviolet (UV) light will depend on local experience and available equipment. One study indicated that UV irradiation gave better hatchability results than washing but was only marginally better than doing nothing at all.⁶⁵ In this study, washing the eggs in a disinfectant bath resulted in decreased hatchability. If washing is required for badly contaminated eggs, the wash solution should be maintained at 40° C to minimize the solution being drawn through the eggshell pores.

Egg Storage

The realities of modern farming practices mean that ostrich eggs should be set only once or twice weekly. This allows a better allocation of labor and other resources. As embryonic development does not appear to proceed at temperatures under 25° C,²⁵ it is feasible to store eggs below this temperature for periods not exceeding 7 days without significant effects on hatchability. A common practice is to store the eggs at 15 to 20° C, turning them twice daily for 3 to 7 days. As the storage time increases, early embryonic mortality rises and can reach 100% by 17 days.²²

Prewarming the eggs prior to storage may increase

hatchability. It has been demonstrated that heating to 36° C for 4 hours prior to less than 6 days' storage at 17° C increased hatchability by 8%. The same study showed that warming stored eggs for 16 hours prior to incubation had no significant effect on hatchability.

Incubator Temperature

Incubation temperatures below those recommended in Table 41.7 may result in slow-developing chicks that hatch late; conversely, temperatures that are too high may lead to premature hatching.

The recommended temperatures may represent a compromise between the higher temperatures required for an early embryo and the lower temperature needed for a late embryo generating its own metabolic heat.²² Most ratite producers compensate for this metabolic heat by moving late-term embryos to a hatcher operating at 1° to 2° C lower than the incubator. These hatchers also operate at a higher relative humidity, and turning is stopped.

Relative Humidity

As the embryo develops, the egg loses moisture (and, therefore, weight) through the shell. Numerous studies have shown that hatchability is maximized when this weight loss is between 12 and 18%. The amount of moisture loss is dependent on the porosity of the shell and the relative humidity of the air surrounding the egg. As most incubators can only increase the relative humidity of room air (they lack the ability to dehumidify it), it is recommended that they be placed in an air-conditioned room fitted with dehumidifiers.

Most ratite eggs incubated at the recommended relative humidity shown in Table 41.7 will lose 12 to 18% of their weight during incubation. However, variables such as shell porosity, altitude, room relative humidity and incubator characteristics can all affect the degree of weight loss. Regular weighing of eggs allows for adjustment of the relative humidity in order to achieve the desired weight loss.

Ventilation

The embryonic cells utilize oxygen, and carbon dioxide is produced. The embryo exchanges these gases initially across the yolk sac membrane and later across the chorioallantoic membrane. Without an efficient exchange, the embryo will die. The rate of exchange is determined by the porosity of the shell and the gas concentration gradient across the shell. It is, therefore, imperative that the incubator maintain a constant flow of fresh air over the eggs, usually achieved by a fan.²⁵ Kiwis are an exception and are best incubated in a still-air incubator. At Auckland Zoo, kiwi eggs are cooled outside the incubator for 1 hour per day during the first 55 days of incuba-

tion.⁶⁶ This simulates egg temperatures recorded in the nest corresponding to the departure of the male for foraging during natural incubation.¹⁹

Turning and Positioning of Eggs

Failure to turn eggs results in poor development of extraembryonic membranes, a reduction in the amount of extra-embryonic fluid produced and poor utilization of albumen by the embryo. Turning is, therefore, essential during incubation up to transfer to a hatcher.^{22,25} Various degrees and rates of turning have been described, but hatchability increases as frequency increases up to 8 times daily. Beyond this, there is little difference in hatchability. The degree of turning is dependent on the frequency of turning, with low-frequency turning requiring large-degree turns.²²

Incubating eggs horizontally for 2 weeks and then vertically for the remainder of incubation appears to maximize ostrich egg hatchability.²²

Kiwis turn their large eggs up to 180 degrees in the early stages of incubation but, due to the imbalance caused by the large air cell, can only rock them from side to side in the later stages. ¹⁹ Artificially incubated eggs are turned on a 2-day cycle, 45 degrees at a time. On the first day, the egg is turned clockwise 90 degrees in two stages and then 90 degrees counterclockwise in two stages. On the second day this is reversed. No turning is done after 55 days' incubation. ⁶⁶

Hygiene

The buildup of microbial contamination can lead to embryonic and chick deaths through bacterial infection. It is, therefore, essential that strict hygiene measures be in place in the incubator room and that the incubator is regularly cleaned and fumigated. Bacterial colony counts can be used as a means of monitoring the level of hygiene in an incubator.²⁵

Monitoring and Record Keeping

Regular assessment of incubating eggs by weighing and candling is essential to detect problems before they become overwhelming. Several advantages of efficient candling practices have been described, and include the early identification and removal of contaminated/infected eggs, early identification of embryonic death at different stages, and the identification of malpositioned eggs.² The ability to make these judgments early allows the early removal of non-viable eggs (thus freeing up valuable incubator space), minimizes contamination and assists in the identification of incubator problems.

Accurate records of setting dates, weight loss, expected hatch dates, outcomes, stages of embryonic death and

Figs 41.11a,b | Brooder shed for ostrich chicks allows sufficient room for exercise. Note the heat lamp.

subsequent chick viability are essential for the clinician trying to assess an incubator problem. Without these records, the task is almost impossible, and much time will be lost monitoring production and generating new records. Producers must have the necessity for good record-keeping strongly impressed on them.

CHICKS

Incubation techniques for ratite eggs have improved to a point where it is reasonable to expect 70 to 90% of fertile eggs to hatch. Adult ratites are generally robust animals with few serious health problems. Chick survivability is, therefore, the greatest limitation to successful production. Reported mortality rates of chicks less than 3 months of age range from 10 to 50%, decreasing to 10% between 3 and 6 months, and 5% up to 12 months.⁶⁸

The ratite chick is precocial, ie, independent of its parents, but its early viability is dependent on the input of the hen into the egg. Calcium for bone development and growth initially comes from the eggshell; minerals, protein and vitamins come from the albumen; fat and immunoglobulins come from the yolk. Therefore, parental nutrition is a key factor in chick survivability. Other factors, such as egg size, weight loss during incubation, microbial contamination and genetics also will have an effect.

Ostrich chicks in particular are susceptible to the effects of stress. Stressors such as temperature extremes, inadequate ventilation, overcrowding, inadequate exercise, poor hygiene, social stresses and incorrect nutrition are all detrimental to growth and survivability of chicks.²⁸ Management of chicks requires that these stressors and others are identified and minimized (Figs 41.11a,b).

While the yolk sac and its contents are important to the chick, the theory that chicks should not be fed for the first few days to encourage absorption of the yolk appears to be incorrect. With the notable exception of kiwis, ratite chicks need to start eating as early as possi-

ble to allow the functional development of the gastrointestinal tract.⁶⁸ They may need an older chick or a chicken to teach them to eat, and the feeding behavior of chicks should be utilized to encourage them to eat as soon as possible. Kiwi chicks begin to probe for food after 5 to 7 days, but rarely begin feeding until their yolks have been fully absorbed at approximately 10 days of age (Jakob-Hoff, personal communication). Because the nutrition of ratite chicks is significantly different from that of adults, dietary management is essential to achieve optimal growth rates. Growth rates of chicks as well as the incidence of problems related to nutrition (such as angular limb deformities) should be monitored.

Many different chick-rearing systems have been used around the world. Concrete runs, sand, bare ground, mobile sheds, permanent structures, lucerne (alfalfa) pasture have all been utilized under different conditions. The one constant seems to be that what works well in one geographical area does not work nearly as well in other areas. Variables such as genetics, climate, available nutrition and labor cost all have an effect on the suitability of chick-rearing systems.

A unifying concept in farmed ratite chick rearing is that of "all in-all out" — the batching of chicks according to their age and body weight and the maintenance of these groups as they progress through the farm system. The advantages of this system have been described and include tailoring the rearing system to the age of the group, moving the birds less so there is less stress, and minimizing the spread of disease by preventing chick movement in or out of the group. A review showed that "mixed weight" groups grew more slowly than "same weight" groups, indicating that social pressures affected the growth of chicks. Such social pressures may be less pronounced in groups of chicks of similar ages and weights.

Management of chicks must aim to minimize stress and maximize growth rates. Biosecurity, vermin control, farm

traffic flow, quarantine and isolation of sick chicks also are necessary to reduce losses due to disease. The integration of these two concepts is paramount to the success of chick rearing.

BREEDERS

Ostriches appear to be induced breeders, ie, the hen requires the stimulation of the presence of a male in order to lay eggs. This makes tools such as artificial insemination, commonly used in the poultry industry, less useful and more complicated.¹⁷ The use of vasectomized "teaser" birds may be one option, but practicality and economics would require fertile cocks to run with egg-laying hens. This can be done as pairs, trios or colonies.

Colonies of ostriches can range in size from 9 to 150 birds, with males making up 20 to 30% of the flock. Although colony breeding is recommended by some authors33 on the grounds of economics, fertility and ease of management, others believe that pairs and trios are more productive. 23,34 Additionally, selection of the best breeding stock requires accurate records of breeding success and chick performance/data that cannot be obtained from colony breeding.

The separation of sexes out of the breeding season and their reintroduction at the start of the season can be a powerful stimulus for breeding.33 This management tool often is overlooked or neglected, usually due to space constraints.

Emus

Emus are primarily monogamous and will pair with only one hen per season. After mating, the cock broods the eggs and takes no further interest in breeding. In this species, artificial insemination may be advantageous.44 Many Australian farms allow breeding birds to run as a flock and then separate pairs as they form. This allows compatibility to develop and retains some degree of genetic selection.

Cassowaries

Cassowaries, by nature solitary and potentially aggressive, may not tolerate the presence of a mate outside the breeding season. This needs to be assessed on a case-bycase basis. Young birds paired early appear to make the best breeders, as adults newly introduced to each other may take several years to develop a pair bond. As the breeding season approaches, cassowaries should be placed within visual proximity to each other, separated by a fence. When they are seen to be interacting, they can share the same enclosure.55

Kiwis

Captive kiwis must be paired carefully. These territorial birds are likely to fight when first introduced and can inflict fatal wounds with their strong feet and claws. Generally, new pairs are established by placing them in adjoining pens so they can hear and smell each other for some weeks to months before an introduction is attempted. Introducing the birds outside the breeding season in a neutral territory and with widely separated feeding stations and roosting boxes can minimize fighting. However, even with these precautions it is important that the introduction and first few nights together be closely supervised, either by video or direct observation. Once the birds have settled down and are eating regularly, a successful pairing can be assumed. Kiwis tend to pair for life, but have been known to form a new pair bond should one of the birds die (Jakob-Hoff, personal communication).

FLOCK HEALTH SCHEMES

With the advent of the commercial phase in ostrich and emu farming, ie, the production of meat and leather as distinct from breeder (investment) birds, the emphasis of veterinary services has moved away from the individual bird to the overall production of the farm. Veterinary input now focuses on areas such as farm design, general management, selection of stock, nutrition, and disease control and prevention.27 An indication of the effect of various parameters on farm profitability is shown in Table 41.8.

These figures are based on production of a farm in South Africa. The magnitude and ranking of these parameters will vary slightly from farm to farm and from country to country. Obviously, some of these, especially the income per slaughter bird, chick mortality rates, hen productivity and feed cost, can have a major impact on profitability. These parameters are well within the capacity of veterinarians to have an effect through a farm flock health scheme. A well-designed and carefully implemented ostrich flock health scheme is a feasible way of achieving improved performance and profitability.7

Before implementing a scheme, the veterinarian first needs to assess the following:

- The farm layout and facility design
- The management practices employed in all aspects of the farm from incubation to breeder management
- The nutritional basis of all rations currently in use
- Complete performance records over the last 2 to 3 years
- Any major problems encountered past or present
- The health status and quality of the ostriches of all ages

Table 41.8 | Effects on Farm Profitability⁷

Parameter	Increase by	Effect on profitability
Income per slaughter bird	10%	55% increase
Chick mortality	10%	35% decrease
Eggs/hen and hatchability	10%	31% increase
Feed cost	10%	27% decrease
Cost of contract work	10%	10% decrease
Labor cost	10%	3% decrease
Cost of drugs	10%	1% decrease

From this, a written plan can be prepared along the following lines:

- Evaluation of the present layout and performance of the farm
- Issues requiring improvement and their relative priority
- Realistic targets for future performance
- Aspects of a flock health scheme required to attain such targets
- Requirements for ongoing monitoring⁷

This plan must take into consideration the farmer's willingness and ability to participate in such a scheme, his/her aims and goals, and the economic realities of implementing the scheme. The scheme must be cost-effective for the farmer or it will not succeed.²⁷

Effective implementation of flock health schemes involving facility design, record keeping, genetic selection programs, preventive health measures, quarantine principles, biosecurity practices, nutritional analysis and monitoring of management practices can improve the efficiency of ostrich farms and increase financial returns to the ostrich producer.⁷

Clinical Examination

DISTANT EXAMINATION AND HISTORY

As with any animal, the examination of a ratite begins with a distant examination and history taking. As most ratites being examined will be farmed birds or zoological specimens, a history of their management, diet, previous medical history and behavior is vital in understanding the problem presented to the clinician.

While taking a history, the clinician is well advised to stand back and watch the bird before capture and restraint takes place. Species' differences in behavior must be understood. For example, it is normal for a cassowary to be isolated and aloof. However, an ostrich that is doing the same may well be ill. Chicks behave differently than adults. Abnormalities in gait, respiration, appetite, posture or feathering often can be best assessed before the bird is

stressed by capture. A fecal examination should be conducted if possible. When as much information as possible has been collected, the bird should be restrained in order to be more closely examined.

HANDLING AND RESTRAINT

Not only are many of the larger ratites capable of inflicting serious injury on people, but also their economic value often lies with the condition of their hide and meat. As such, handling and restraint techniques must ensure that no harm befalls either the bird or the people doing the handling. Time spent planning and preparing to work with a ratite is never wasted!

Wherever possible, adult ostriches should be removed from their own enclosure (which they have come to regard as their territory) before an attempt is made to handle them. If time permits, allowing the birds to become accustomed to being fed in a smaller enclosure (eg, a shed or mobile cattle yard) for a few days can make capture simple and safe. Once the birds are comfortable entering the enclosure, merely closing a gate behind them can capture them. If time does not allow this approach, several people working together can herd the birds into a corner of the pen or into a small enclosure. As ostriches are quite adept at running past individual handlers, creating a "mobile fence" by suspending a length of shade cloth between handlers can effectively herd the birds to where they can be captured. This whole procedure must be done calmly and smoothly, with a minimum of running, shouting and arm-waving.

Once confined, individual ostriches can be caught and examined. An ostrich is generally more amenable when it is "hooded", ie, a tubular cloth hood is placed over its head restricting its eyesight. To do this, the neck is grasped just below the head, either by hand or with a shepherd's crook, and the head is pulled down to a horizontal plane (Fig 41.12). Care must be taken not to damage the neck and jugular vein, as fatal hematomas have resulted from trauma to the vein by careless handling. The handler has the hood bunched up over the free hand, which then grasps the beak (Fig 41.13). The hood is then pulled over the head and the head is released. The ostrich is then immediately restrained with a hand on the cranial sternum and another on the pubic bones. Large birds may require two handlers, one on either side of the bird. Under no circumstances should the bird be given the opportunity to run while hooded, as injury invariably results.

Emus

Emus do not tolerate a hood, although Jakob-Hoff (personal communication) has found them useful as long as

Fig 41.12 | Capture and restraint of an ostrich using a "shepherd's crook" and a hood.

Fig 41.13 | Preparing to place a hood on an ostrich.

the hooded bird, can detect no light. Once placed in a small enclosure, approaching an emu from behind and hooking an arm around the base of the neck near the thoracic inlet can restrain it. The bird is pulled back against the handler's body and the other hand is used to grasp the upper neck. The bird is then tilted backward into a more human-related upright position relative to the normal emu body position. Once it has settled, the upper neck can be released.⁴⁵

Cassowaries

Cassowaries are dangerous to handle. Physical restraint can be achieved by herding the bird into a corner. The handlers use padded sheets of plywood to block the bird. They must be braced against the impact of a running or jumping bird, and the handlers must be aware of the cassowary's ability to jump. Once the bird is cornered, it can be approached from behind and pushed firmly to the ground by applying body weight squarely onto its back. Once it is sitting, a second person can restrain the tarsometatarsus to immobilize the bird. Care must be taken not to injure the leg. A hood can be tried, but not all birds will tolerate it.55 Chemical sedation may be required for further examination. This can be given after physical restraint or by darting before examination. Ketamine, diazepam, xylazine and zolazepam-tiletamine have all been used with unpredictable results. Medetomidine was trialed at 0.26 to 0.31 mg/kg (captive birds) and 0.38 to 0.54 mg/kg (free-ranging birds) with good results.70 External stimuli must be avoided once the birds are sedated to avoid auditory stimulation.

Kiwis

Kiwis are easily restrained by grasping both legs above the hock joint between the thumb and middle finger of the right hand with the index finger between the two legs (Fig 41.14). The left hand supports the ventral and lateral body into a sitting posture in the crook of the right elbow. Directing the bird's bill and eyes under the cover of the left arm while in this position will help calm it. An alternative method, used when handling kiwi in the field, is to grasp the two legs as described and hold the bird in the upside-down position. The dorsal body is then placed on the lap of the holder with the head similarly placed under the left arm. The birds tolerate this remarkably well for the considerable period of time it takes to apply a radio transmitter and take measurements and diagnostic samples (Jakob-Hoff, personal communication).

PHYSICAL EXAMINATION

Once the bird has been safely restrained, the physical examination can proceed (Table 41.9). A systematic and thorough evaluation is essential, and the use of a comprehensive examination form can be invaluable. A detailed guide to the examination of the ostrich is available. A summary of this technique can be applied to all ratites. After the bird is caught and identified (leg band, microchip), the following are performed:

- Externally examine the eyes, beak, nares, ears and oral cavity.
- Check the body condition by palpating the spine.
- Auscultate the thorax, determining the heart and respiratory rates and checking for abnormal respiratory and cardiac sounds at several sites.
- Auscultate the proventriculus and ventriculus.
- Palpate the abdomen, including the proventriculus and ventriculus.
- Observe the feet and legs for abnormalities.
- Palpate the limbs and determine the alignment of the tibia.
- Examine the skin and feathers for abnormalities and parasites.
- Examine the vent and digitally sex the bird.

Fig 41.14 | Examining a kiwi chick at Auckland Zoo.

Fig 41.15 | The basilic vein is suitable for blood collection only in the ostrich.

Table 41.9 | Some Physical Characteristics of Adult Ratites

	Weight (kg)	Heart Rate	Respiratory Rate
Ostrich	80-150	30-60	6-12
Emu	35-55	42-76	13-21
Cassowary	85	35-90*	20-44
Rhea	25	_	_
Kiwi	1.5-4.0	70-240	12-60

^{*}Recorded under sedation

Clinical findings should be recorded as the examination proceeds, especially if there are several birds to be examined at the same time. A standardized examination form is invaluable in this respect; not only does it allow accurate recording, it also ensures the clinician does not overlook part of the examination (see Chapter 6 Maximizing Information from the Physical Examination).

DIAGNOSTIC TESTING

If appropriate, samples for laboratory analysis can be collected following the examination.

Several veins are readily accessible for venipuncture in ratites other than the kiwi. The right jugular vein is suitable for the smaller ratites and juveniles. Care should be taken in the larger ratites, because the thin-walled jugular can tear easily, leading to a potentially fatal hematoma. The basilic vein can be used in ostriches (Fig 41.15), but the small vestigial wings in other ratites make this vein unsuitable in other species. The medial metatarsal vein is accessible in all species, but care must be taken that adequate restraint is in place before this vein is utilized. In kiwis, this is the only usable vein (Fig 41.16), the jugular being inaccessible due to the overlying layer of thick, fatty skin (Jakob-Hoff, personal communication).

A blood smear should be made immediately and the rest of the sample placed in plain tubes or, preferably, lithium heparin. If the samples cannot be analyzed rapidly, it is advisable to centrifuge the sample and refrigerate the plasma or serum.

Fig 41.16 | Kiwi dissection shows the medial metatarsal vein, the only accessible vein for blood collection in this species.

In ostrich hens with a history of reproductive disease (embryonic deaths, poor shell quality, irregular laying, misshapen eggs), a swab can be taken of the distal oviduct for cytology and culture. With the hen hooded and perhaps restrained, a gloved and lubricated hand is placed into the urodeum, and the oviduct opening is located. This opening is found in the 10 o'clock position in a small papilla. A finger can be passed through this opening into the distal oviduct and a guarded mare swab introduced alongside the finger. A limitation of this technique is that only the caudal 10 to 15 cm of the oviduct can be accessed; a disease process occurring more proximally may be missed. Common pathogens isolated include *E. coli*, *Pseudomonas* spp. and *Klebsiella* spp. Fecal contamination is not uncommon.⁴

Several authors have described semen collection in ostriches. 4.26,36 It should be attempted only in mature, reproductively active birds; young or sexually inactive birds will produce little or no semen. Although artificial insemination techniques are being developed in ostriches, semen collection and assessment are important parts of an infertility assessment. Minimal restraint should be

used, as excessive stress may inhibit ejaculation. The administration of 5 to 10 IU of oxytocin intravenously may produce a better sample.60 The phallus is manually extruded from the cloaca, and the dorsal base (where the ductus deferens papillae are located under the uroproctodeal fold) is gently but firmly massaged. Ejaculation occurs after a variable time period, and the semen can be collected as it runs down the dorsal phallic groove.

The use of an artificial cloaca to collect semen in emus has been described.⁴⁴ Using a "teaser" hen, the artificial cloaca is placed over the phallus as the cock attempts to mate with the hen. This technique has been quite successful in collecting from these birds.

Interpretation of Clinical Pathology

The interpretation of hematology and biochemistry in ratites is very similar to that of other avian species. It should be noted that ratites normally have much higher creatine kinase (CK) values than other avian species. Table 41.10 shows reference ranges for ratite species. An excellent guide to the interpretation of ratite clinical pathology also is available.32

NECROPSY TECHNIQUES

As the ratite industries become more commercial, the value of the necropsy to quickly and accurately determine a diagnosis and etiology continues to grow (Fig 41.17). Necropsy offers both the most accurate diagnosis and the most cost-effective option. These advantages should be impressed on both farmers and zookeepers. and the value of having both fail-to-hatch eggs and dead birds submitted for veterinary examination emphasized.

Egg Necropsy

All eggs that fail to hatch should be necropsied. Not only

does an egg necropsy allow a determination of the stage and possible cause of embryonic death, it also provides the clinician (and farmer) with a true indication of fertility. On several occasions, this author has been asked to investigate infertility problems, only to discover (via egg necropsy) that the problem was actually one involving embryonic mortality.

The technique is simple. The egg is first weighed and, if possible, the weight loss during incubation is calculated. The shell quality is examined (surface texture, porosity and cleanliness). The egg is then candled. Candling allows identification of the air cell, an indication of its size and mobility, and an idea as to whether an embryo or infection is present. Hairline cracks in the shell also can be identified. This information is recorded and then the next step is taken.

The egg is placed vertically onto a support (a ring of PVC pipe is sufficient) with the air cell uppermost. The shell over the air cell is broken with a drill or a sharp tap of a hammer, revealing the air cell. The shell is then broken away to the level of the inner shell membrane forming the base of the air cell. This membrane is peeled away with fine forceps, revealing the egg contents (Fig 41.18a).

At this stage, a swab for culture of bacteria and fungi can be taken from the albumen or inside the shell. If an embryo is not obviously present, the blastodisk on the yolk should be examined. The yolk around this disk is less dense than the rest of the yolk, so it will float uppermost. In an infertile egg, the disc will appear as a small white point. A very early embryo will appear as a small white "doughnut" with a patch of yolk in the middle. Any blood vessel development at all is confirmation of fertility (Fig 41.18b).

Fig 41.17 | This intra-abdominal fat in a mature ostrich at slaughter represents a significant financial loss to the farmer in wasted food conversion.

If an embryo is present, two determinations must be made: the positioning of the embryo (if it is late term) and the stage of development.

Embryonic position is observed before removing the embryo from the egg. The normal late-term embryo is positioned with the head next to the air cell, right side uppermost and turned to the right, with the beak adjacent to the right foot and shoulder; legs flexed on either side of the body and ventral to the shoulders; and the spine following the long axis of the egg. Any other position is classified as a malposition, and may account for embryonic death. Descriptions and possible causes of classical malpositions are described in Table 41.11.

A measurement of the embryo's crown-to-rump length and an assessment of its growth and development can give an indication as to whether this is an early, midterm or late-term embryo.

A procedure for egg necropsies has been described.¹² In summary, once the embryo is removed from the egg, the following procedure is recommended:

- Record position of yolk sac and percentage that is external.
- 2. Weigh embryo and record crown-to-rump length.
- 3. Measure thickness of edema (if present) over proximal neck and thighs.
- 4. Remove and weigh yolk sac (if necessary, incise abdomen).
- 5. Record gender.
- 6. Collect samples from the chorioallantois, yolk and proventriculus for culture.
- 7. Collect tissues from multiple organs, including the membranes, in formalin.

By determining the stage and cause of embryonic death, the clinician can then start to narrow down the search for

Figs 41.18a,b | An egg necropsy can identify early embryonic deaths in fertile eggs: **a)** degenerated germinal disc; **b)** degenerating vessels.

the underlying cause of embryonic mortality (Table 41.12).

Necropsy of Chicks and Older Birds

As with any necropsy, a thorough and methodical procedure is essential to obtain the best results. If the bird is still alive, it should be weighed (if possible) and blood collected for hematology and biochemistry. A physical examination should be conducted and then the bird humanely euthanized. Care must be taken to ensure that the euthanasia method does not affect likely necropsy findings.

The body can be opened through a midline incision with the bird in dorsal recumbency, but an alternative is a lateral approach. The body is placed in lateral recumbency, the upper leg is abducted, and an incision is made along the ventrolateral border of the body. The skin is reflected, the coxofemoral joint is disarticulated and the leg is further abducted. The abdominal muscles and ribs can then be transected and reflected dorsally. This gives a good exposure of the internal organs.

Table 41.11 | Embryonic Malpositions

Malposition	Description	Possible Causes (if known)
I	Head is down between the legs	High incubator temperature
II	Chick is rotated within the egg, with the head at the end opposite to the air cell	Egg position and low temperature during incubation
III	Head is rotated to the left, with the head under the left wing	Egg position, temperature and parental malnutrition
IV	Beak is away from the air cell, rest of the body is normally positioned	Egg position
٧	Feet over the head	_
VI	Head over the right wing	Parental nutrition

The relative size and position of the organs is noted, and culture swabs are taken from the liver and proventriculus. Individual organs are removed and examined, and tissue samples are placed in formalin for histological evaluation. Proventricular contents should be examined and the contents assessed for possible impaction. Intestinal contents should be assessed as to consistency and volume. A written report should be prepared and placed in the farm's records.

Diseases of Ratite Chicks

Studies of ostrich chick mortality indicate that most deaths occur before 2 months of age and that chicks of this age are most likely to die of infectious diseases. After 2 months of age, death is usually the result of leg problems. Mortality rates from all causes drop significantly after 4 months (More, personal communication). In South Africa, chick mortality is reported to be as high as 40 to 50% up to 3 months and 10 to 30% from 3 to 6 months. Mortality from 3 to 12 months dropped to 5%.68 Problems with chicks are a major limiting factor in successful ratite production.

DISEASES OF THE INTEGUMENT

Congenital deformities of the beak are occasionally seen in ostrich chicks. The more common of these deformities include scissor beak and a downward deviation of both rhinotheca and gnathotheca. These rarely cause any significant problems to the chick, and treatment is rarely warranted. Severe deformities can interfere with the prehension of food and, unless the chick is valuable, euthanasia may be the preferred option. Manganese deficiency in parental diets is reported to cause a shortening of the lower beak.34

Mycotic dermatoses involving Aspergillus spp., Trichophyton spp. and Microsporum spp. have been reported.34 Treatment with 10% enilconazole washa is the recommended treatment.

Table 41.12 | Troubleshooting Embryonic Mortality^{40,64}

	• • • • • • • • • • • • • • • • • • •
Problem	Possible Causes
Floating air cell	Rough handling of eggParental nutritional deficienciesGenetics
Early embryonic mortality	Parental nutritional deficiencies Delayed egg collection Incorrect storage – temperature incorrect, stored too long Shaking/jarring of eggs Incubator problem – temperature, turning, ventilation Formaldehyde fumigation of eggs in first 3 days
Mid-term embryonic mortality	Parental nutritional deficiencies Infection Inadequate turning Incubator problem – temperature, turning, ventilation Lethal genes
Late-term embryonic mortality	Malpositions Incubator problem – temperature, humidity, turning, ventilation Infection Parental nutritional deficiencies
Air cell pip, fail to hatch	Hatcher problem – temperature, humidity, ventilation
Malformed chicks	Incubator temperature too high Parental nutritional deficiencies Genetics Teratogens
Edematous chicks	Humidity too high Shell too thick Inadequate ventilation
Sticky chicks	Humidity too high Shell too thin
External yolk sac	Temperature too high Edematous chick Inappropriate intervention to assist hatch

Avipoxvirus has been reported in ostrich chicks in South Africa, Israel, the United States and Australia. 53,58 The proximity of poultry and the presence of suitable vectors contribute to outbreaks. Chicks from the age of 2 weeks are affected, with both cutaneous and diphtheritic forms reported. Vaccination from 10 days of age with fowl pox vaccine combined with biting insect control will usually limit or prevent outbreaks.

Hyperkeratosis of the skin around the head, eyelids, beak commissures, neck and feet has been observed in ostrich chicks and is thought to be nutritional in origin. Supplementation with zinc and biotin often is curative. It must be distinguished from mycotic infections.

A biotin-responsive plumage abnormality has been recorded in wild-hatched North Island brown kiwi chicks simultaneously parasitized by a hemoparasite of the genus Babesia. The feather abnormalities included complete feather loss from the ventral-lateral trunk and thighs and retention of keratinized sheaths on dorsal contour feathers, giving the plumage a dry, spiky texture. The hemoparasite infection was associated with pronounced pyrexia, and it was speculated this might have interfered with biotin absorption as has been recorded in poultry.38

DISEASES OF THE GASTROINTESTINAL TRACT

Candidiasis in ratite chicks can result from immunosuppression, malnutrition or prolonged antibiotic therapy. Plaque-like lesions can be observed in the oropharynx, although the infection can extend through to the ventriculus. Cytology and/or culture are diagnostic. Treatment with nystatin or ketoconazole is usually successful.

Other fungal infections, including zygomycosis and macrorhabdosis (megabacteriosis), have been reported in ostrich chicks.^{34,58} Treatment is the same as in other avian species.

Bacterial enteritis is a common problem in ostrich chicks (Fig 41.19). *Salmonella* spp., *E. coli* and *Pseudomonas* spp. are the most common isolates. Clinical signs are not limited to just the intestinal tract, as septicemia frequently develops. Diarrhea, swollen joints, keratitis, corneal ulceration, depression and anorexia are common clinical signs. Hepatic granulomas are frequently seen on necropsy of chicks dying from *Pseudomonas* septicemia or colibacillosis. Although antibiotic therapy, based on culture and sensitivity testing, can save some chicks, severely affected birds usually die. It is essential that investigating clinicians do all that is possible to identify the source of the infection, as management issues significantly contribute to such outbreaks.

Clostridial enteritis may be an over-diagnosed problem. Clostridium perfringens is a normal inhabitant of the ostrich intestinal tract and its identification on fecal culture does not necessarily constitute a diagnosis of clostridial enteritis.34 Abrupt dietary changes, starvation, stress, anthelmintics and vaccinations have been associated with outbreaks. Ingestion of soil and substrate contaminated with clostridial spores also may be a contributing factor. Acute mortality, occasionally with antemortem anorexia and depression, is the hallmark of this infection. Necropsy reveals varying degrees of enteritis associated with clostridial spores, and Clostridium spp. can be cultured from affected chicks. Treatment with tetracycline, penicillin and zinc bacitracin has been described.34,58 A vaccination protocol using Cl. perfringens Type B and D vaccines at either 1 week or 1 month, or at 3 and 6 weeks, also has been described.34

Adenoviral enteritis has been described in ostrich chicks in the USA.⁵⁴ Affected chicks, usually older than 2 months, show marked depression, anorexia and diarrhea. Mortality is usually greater than 90%. Vertical and horizontal transmission can occur. Infectious bursal disease has been reported in the United States. Affected chicks show depression, anorexia and diarrhea over a 3-to 4-day period before death.⁵⁸

Fig 41.19 | Intestinal volvulus in a 6-week ostrich chick. This may be secondary to enteritis and is usually diagnosed postmortem.

Endoparasitism can be a major problem in young ratites, particularly if they are reared with adults or have access to adult fecal material. An excellent review of ratite parasites is available. Libyostrongylus douglassii (wire worm) is a major problem on some ostrich farms on most continents, with mortality rates of affected chicks approaching 50%. It causes a diphtheritic proventriculitis (vrotmaag: rotten stomach), with clinical signs including weight loss, depression, anorexia and death. Strongyle eggs identified on fecal flotation should be cultured, as larval identification is needed to diagnose *L. douglassii*. Levamisole, fenbendazole and ivermectin have been reported as effective treatments.

Many other helminths have been identified in ostriches and other ratites, including trichostrongyles, ascarids, acanthocephalans and cestodes. Protozoal parasites, including *Cryptosporidia*, *Balantidium* spp., *Histomonas meleagridis*, *Spironucleus* and coccidia, have been reported in many ratite species. Coccidiosis is by far the most important gastrointestinal parasite of captive kiwis, and regular monitoring is important. Cumulative fecal samples collected over 4 days are examined to reduce the possibility of missing this intermittently shed parasite. The infestation is readily treated with a single dose of toltrazuril^b (25 mg/kg PO).³⁷

Prolapses of the cloaca and rectum in young chicks can occur secondarily to enteritis. Treatment of these prolapses involves replacement with a gloved, lubricated finger and correction of the initiating cause. If the prolapse recurs, the use of a purse-string suture may be required. This suture can be placed under local anesthesia and should be left in place for no more than 3 days (Black, personal communication).

Treatment of enteritis in ostrich chicks revolves around

several key principles: early recognition that a problem exists; identification and isolation of affected chicks; identification of the causative pathogen; and appropriate treatment.

Batching of chicks and good biosecurity measures offer the best chance of success in stopping an outbreak.

DISEASES OF THE RESPIRATORY **SYSTEM**

The artificial environment in which young ratites are usually reared — hatchers, brooders and chick pens often are poorly ventilated, and respiratory disease results.

Aspergillosis is a common disease in ratites (Fig 41.20). Aspergillus fumigatus and A. flavus are commonly isolated from affected birds; A. niger and A. terreus may not be clinically significant (Black, personal communication). In chicks, the disease is associated with poorly ventilated hatchers and brooders. Eggs contaminated with Aspergillus spp. from nest substrate placed in a hatcher cause a buildup of spores, which are then inhaled by newly hatched chicks. Alternatively, chicks placed in poorly ventilated, unhygienic brooder pens may be exposed to spores. If an immunocompromised chick inhales sufficient spores, an overwhelming fulminating "brooder pneumonia" may result, often followed by relatively acute death. In other cases, an air sacculitis may result, which may not become clinically apparent for weeks, months or even years. Treatment is usually unrewarding because of the often chronic, granulomatous nature of the disease. Ketoconazole, amphotericin B and itraconazole have been used to treat systemic aspergillosis, while inhalation of smoke generated by enilconazole bombs^c have been used to treat pneumonia and air sacculitis.

Pseudomonas aeruginosa, Pasteurella baemolytica, P. multocida, Haemophilus spp. and Bordatella spp. have been isolated from chicks with respiratory infections.34 Mycoplasma spp. also has been isolated.

An important factor in the pathogenesis of respiratory disease in ratite chicks is ammonia toxicosis. Ammonia arising from the feces and urine builds up in chick sheds overnight when the chicks are closely confined. Overcrowding and poor ventilation in the shed will lead to ammonia toxicosis. This should be suspected when, upon opening the shed in the morning, the chicks are lethargic and yawn frequently. In more severe cases, keratitis may develop. The smell of ammonia in the shed is strong. The irritation to the airways can lead to secondary infections as described above. Prevention revolves around management: overcrowding should be avoided

Fig 41.20 | An ostrich hen with advanced aspergillosis exhibits severe respiratory distress.

(allow 0.5 to 1.5 m² floor space per chick). Chick sheds should be cleaned daily to reduce the buildup of feces and urine, and ventilation should be improved. As ammonia is heavier than air and will therefore settle closer to the floor, ventilation must be provided at chick level. Ventilation grills 15 to 30 cm above the floor combined with exhaust vents in the roof can dramatically improve the situation.

DISEASES OF THE YOLK SAC

The newly hatched chick receives some nutrients and possibly immunoglobulins from the yolk sac, which is attached to the intestine via the vitello-intestinal duct. Yolk sac contents are drained by this duct and via absorption by mesenteric blood vessels around the volk sac. A few days before hatching, the yolk sac is drawn into the abdomen, and the abdominal muscles close over it at the navel. The volk is resorbed over 10 to 14 days, and only a vestigial remnant remains after 3 weeks.

Occasionally the umbilicus fails to close fully, exposing a portion of the yolk sac. If the exposure is only small, dressing it with iodine and bandaging until closure is complete may be all that is required. Larger exposures may require surgical correction if economically practical. Affected chicks should be monitored carefully for omphalitis or yolk sac retention.

Omphalitis, or yolk sac infection, can be a multifactorial problem seen in chicks less than 1 week of age. Chicks that have been stressed by incorrect incubator/hatcher temperature and humidity or chicks that are weak or undersized at hatch are predisposed to bacterial infection. This infection usually arises from poor hygiene in the hatcher or brooder, although transovarial and transoviductal infections and shell contamination also can be involved. Many chicks that develop yolk sac retention may subsequently develop omphalitis. The incidence on

Table 41.13 | Prevention of Omphalitis and **Yolk Sac Retention***

- · Optimal incubation conditions
- · Avoidance of early or inappropriate intervention during hatching (an exposed yolk sac has a much higher chance of becoming infected)
- Good hatcher hygiene
- Minimal handling after hatching
- · Adequate umbilical care
- Adequate nutrition and exercise
- *Black (personal communication)

many farms can be reduced by correcting incubator and hatcher problems and hygiene and applying an iodine ointment and bandage to the umbilicus of newly hatched chicks (Table 41.13). If chicks from a particular hen show a high incidence of omphalitis (without other chicks being affected), that hen needs to be investigated for the possibility of salpingitis.

Yolk sac retention, on the other hand, is a failure of the yolk sac to be resorbed in the absence of infection. This is primarily a management problem, with possible faults lying in incubator or hatcher problems, chick nutrition and exercise. Unless secondary omphalitis develops, clinical signs do not become evident until the chick is 2 to 6 weeks old and the autolyzing yolk begins to release possible toxic substances that are absorbed by the mesenteric blood vessels. These chicks fail to thrive and usually start to lose weight. The yolk sac often is palpable in the abdomen or is detectable via ultrasound.

As antibiotics do not penetrate the yolk sac, treatment for both omphalitis and yolk sac retention is the surgical excision of the volk sac. Although a relatively simple procedure, the success rate for omphalectomy is not high due to pre-existing toxemia and immunosuppression.

DISEASES OF THE MUSCULOSKELETAL SYSTEM

"Wry neck" or torticollis is seen occasionally in all ratite species, with emus been the most frequently affected. The muscles and tendons of the neck cause abnormal positioning of the neck and head. Suggested etiologies include vitamin E and selenium deficiencies, teratogens, parental malnutrition, excessive handling and turning of the egg during incubation, and skeletal malformation. Splinting and dietary supplementation may improve many chicks.61

Tibiotarsal rotation (or angular limb deformity) is one of the most common and serious limb deformities seen in ratite chicks (Fig 41.21). The tibiotarsus rotates along its long axis, leading to an outward rotation of the limb (Fig 41.22). Mild cases may show only a "windmilling" gait when running, ie, the affected leg swings out rather than going straight ahead. Severe cases may be so badly rotated that the chick has great difficulty in walking and standing. Numerous causes have been suggested, indicating this problem's multifactorial nature. Possible etiologies may include diets excessively high in protein and/or energy, calcium/phosphorous imbalances, leg injuries, lack of exercise and heating of chick pen floors. Although no hereditary component has been conclusively identified, it appears that certain breeding pairs may produce offspring that have a high growth rate. These offspring, if fed a diet that can maintain or encourage this high growth rate, will develop a higher incidence of tibiotarsal rotation if they are exercised inadequately. Various surgical corrections have been described, but none has shown consistent long-term success. In kiwi chicks, "splayed legs", which occur when the brooder box substrate is too slippery to afford adequate traction, can readily be corrected with hobbles if identified in the early stages (Fig 41.23) (Jakob-Hoff, personal communication).

Fig 41.21 | Angular limb deformity in an ostrich chick raised on an oxalate-rich pasture, causing calcium deficiency.

Fig 41.22 | Bowed tarsometatarsus, mature ostrich. This is usually the result of juvenile nutritional imbalance.

Fig 41.23 | Splay leg in a young kiwi chick. At this age, this condition is reversible through the application of hobbles and use of a non-slip substrate.

Rickets is the result of a deficiency of vitamin D₃. This can be due to dietary imbalances, lack of sunlight or intestinal malabsorption. It results in enlargement of the joints and bowing of the femur, tibiotarsus and tarsometatarsus.61 Identifying and rectifying the inciting cause(s) may correct early cases. Other causes of bowed legs include nutritional calcium and phosphorous deficiencies or imbalances.

Rolled toes appear to occur in two distinct groups. The first group is chicks aged less than a week. Within a day or two of hatching, the toe begins to roll medially. Parental malnutrition and incubator errors have been implicated as causative factors. Corrective splinting or taping of the affected toe usually rectifies the roll within a few days. Chicks older than 4 to 5 weeks make up the second group. In these chicks, the rolled toe appears to be a variation of the angular limb deformity problem. Splinting may help with these chicks, but the prognosis is not as good unless dietary and exercise factors are corrected.

"Slipped tendon" refers to the lateral luxation of the flexor tendon of the gastrocnemius muscle out of its position on the caudal aspect of the hock joint. This can be mild, with immediate relocation of the tendon when the joint is straightened, or so severe that the tibiotarsus tears through the skin. Acute, mild cases may be successfully treated with bandaging and splinting. More severe cases, or cases where the luxation has been present for several hours, carry a poor prognosis. Surgical repair of the tendon retinaculum is required in these cases but is usually unsuccessful because of the weight-bearing stresses placed upon it.

OSTRICH FADING SYNDROME (CHICK FADING SYNDROME)

In the early 1990s, a syndrome in ostrich chicks less than 6 months old, characterized by weight loss, anemia and death, started to appear on ostrich farms throughout the world. Mortality rates vary from 20 to 80%. Affected chicks progressively lose weight with wasting of the paralumbar muscles. Ascites often develops. Urate pasting around the vent is common as the chick weakens. A nonregenerative anemia is a frequent clinical finding.

Necropsy reveals a multitude of pathologies including rhinitis, pharyngitis, proventriculitis, enteritis, pneumonia, air sacculitis, hepatic abscessation and splenic atrophy. The most consistent histological finding is non-suppurative enteritis.13

The syndrome appears to have an infectious etiology, but numerous pathogens have been recovered from affected chicks: Cryptosporidia, gram-negative and gram-positive bacteria, fungi and yeast, and a range of viruses. No consistent pathogen has been identified. 13,61

Given the wide range of findings and secondary pathogens isolated, it is generally presumed that a primary immunosuppressive agent is responsible for this syndrome. Work in Australia suggested that a retrovirus may be the causative agent, but this has yet to be confirmed.⁴⁸

A major problem with this disease is the tendency of many farmers to categorize all chick mortalities as fading syndrome and decline further work-up. Clinicians must educate their clients against this tendency. The good news is that in recent years the incidence of this disease appears to have declined. Until the causative agent is identified, good biosecurity measures and treatment of secondary pathogens is the best that can be offered.

Diseases Of Adult Ratites

Mortality rates in ostriches decline rapidly with age. This appears to apply to all ratites, with few of the disease processes described for chicks applying to adult birds. Discussed below are some of the problems specific to adult birds, as well as some that can affect all age groups.

DISEASES OF THE INTEGUMENT

Skin lacerations are not uncommon in captive ratites, often occurring as injuries inflicted by collisions with wire fences. Although these respond well to basic treatment principles, it must be noted that scarring will significantly detract from the hide value in birds such as ostriches and emus. Fence construction and handling procedures must be done with the aim of minimizing such injuries.

Bacterial and mycotic dermatitis and folliculitis do not appear to be common but can occur in excessively humid climates. Early recognition and treatment is essential to prevent or minimize damage to the hide.

An exudative dermatitis beginning around the external auditory meatus and progressing to involve the ventral and dorsal neck has been reported in captive kiwis whose normal vitamin/mineral supplement had been accidentally omitted from the diet. The condition responded dramatically to B-complex vitamin injections after 5 to 6 days.¹⁰

Ectoparasites are common in ratites, with ticks, lice and mites being found on most species. While the primary clinical focus is on the damage caused to plumage and hide by lice such as the ostrich louse, *Strutbioliperirus strutbionis*, and mites such as the quill mite, *Gabucinia bicaudatus*, other problems have been recorded. Tick paralysis, caused by an ixodid tick, *Hyalomma truncatum*, has been reported in South Africa, while an argasid tick, *Argus persicus*, can cause anemia in chicks and transmit aegyptianellosis from chickens to ostriches.²¹ The kiwi tick, *Ixodes anatis*, is suspected to be the vector of the *Babesia* spp. found in these birds.⁵⁰ Regular spraying with 2% malathion or pyrethrins needs to be part of the husbandry of ratites.

DISEASES OF THE DIGESTIVE SYSTEM

Mycobacterial infections have been reported in ostriches, emus, cassowaries, rheas and kiwis.^{29,34,58} Affected birds typically show chronic weight loss accompanied by a marked leukocytosis. Necropsy shows multiple granulomas throughout the liver parenchyma and intestinal serosa, extending into the mucosa. *Mycobacterium avium* is usually identified either by culture or PCR. Although some reports⁵⁸ contend that intradermal tuberculin testing is diagnostic, this is not confirmed by other reports.²⁹ At this time, intradermal testing should be used to confirm the presence of the disease in a flock, rather than in individuals. Although the zoonotic potential of *M. avium* strains isolated from ratites has not been fully ascertained, treatment is not recommended and affected birds should be euthanized.

Sick or stressed ostriches of all ages may start to ingest foreign or indigestible material, which blocks (impacts) the proventriculus. As more material (high-fiber grasses, stones, dirt, sticks) is added, the proventriculus becomes distended, but no ingesta can move through. Affected birds become anorectic, weak and lose weight. They may regurgitate water after drinking. Fecal output diminishes or ceases altogether. The impacted proventriculus is usually palpable. Young birds can be treated by gastric

lavage while suspended upside down. Older birds may require a proventriculotomy.³⁴ Although some authors³⁴ advocate against the use of mineral oil, it has been used successfully in sand and gravel impaction when combined with psyllium (Doneley, personal observation). Treatment is of value only if the original stressor has been removed, behavioral stress minimized and access to substrate and/or foreign material prevented.³⁵

Eastern equine encephalitis (EEE) has been reported in emus in North America. Affected birds show depression, recumbency and hemorrhagic diarrhea, followed by death. Prevention revolves around minimizing exposure to biting insects and a vaccination protocol using a commercial equine inactivated EEE vaccine.⁵⁸

An acute central nervous system disease manifesting as extreme depression and convulsions has been observed in a number of captive North Island brown kiwi. Some fatalities have occurred while others have made a full recovery over a number of days to weeks with supportive care. Although response to antibiotics has suggested a bacterial etiology, not all affected birds responded similarly (Jakob-Hoff, personal communication).

DISEASES OF THE RESPIRATORY SYSTEM

The most common respiratory disease seen in ratites is air sacculitis associated with infection by Aspergillus spp. Unlike the "brooder pneumonia" seen in young chicks, this is a chronic disease with clinical signs often appearing within a few weeks of a stressful event such as transport. Affected birds lose weight and show an increased respiratory effort, seen as an increased respiratory rate (greater than 20 breaths per minute in a non-stressed bird), increased sternal lift and open-mouth breathing. Care must be taken to observe suspect birds before they are handled or heat stressed, as this can replicate the signs of respiratory distress. Some birds may cough. Auscultation over the paralumbar fossa may detect rasps, squeaks and friction rubs at peak inspiration and expiration. Leukocytosis is frequent, but serology is unreliable, as many birds appear to fail to seroconvert and will test falsely negative.

Aspergillosis is not contagious among birds, but it is not uncommon to find several birds infected from a common source. Treatment with antibiotics (for secondary infections), itraconazole orally and fumigation with enil-conazole smoke bombs^c appears to be effective in causing remission of clinical signs in many birds, although recurrence months or years later is common (Doneley, personal observations).⁴³

Avian influenza, caused by a number of strains of the

influenza virus, has been reported in ostriches in South Africa and Denmark. Chicks are apparently more susceptible than are adults, but all age groups can be affected. Clinically, infected birds show severe depression, respiratory signs, ocular discharge and green urates. Treatment is usually unsuccessful, and vaccination relies on the identification of the viral strain present. Prevention is best achieved by preventing contact between ostriches and free-ranging birds.³⁵

DISEASES OF THE NERVOUS SYSTEM

Newcastle disease, caused by paramyxovirus serotype 1 (PMV1), has been reported in ostriches in Africa and Israel and in rheas in Brazil. The virus is documented in 236 avian species, confirming widespread susceptibility of birds to this disease. See Young birds appear to be more susceptible, with up to 50% mortality. Affected birds initially show a slight head tilt, frequent scratching of the head and a tic of the neck muscles. This progresses on to torticollis, uncontrolled head movements and finally an inability to lift the head off the ground. Death occurs in 2 to 3 days. There is no treatment, although some birds recover spontaneously. Vaccination is carried out on some farms in South Africa with apparently good results. 9,57,67

Western equine encephalitis (WEE) has been reported in emus and rheas in North America.⁶⁹ Affected birds are initially depressed, progressing on to paresis, recumbency and finally paralysis. Mortality rates are less than 20%, with recumbent birds dying within 48 hours. Vector control and vaccination are usually effective in preventing this disease.⁵⁸

Borna Disease is seen in 2- to 8-week-old ostrich chicks in Israel. Affected chicks show paresis and reluctance to move, progressing on to paralysis and finally death from dehydration.⁵⁸

Cerebral nematodiasis has been reported in ostriches and emus in North America. *Chandlerella quiscali* and *Baylisascaris* spp. have been isolated from birds showing signs including ataxia, abnormal gait, muscle weakness, recumbency and death.²¹

DISEASES OF THE REPRODUCTIVE SYSTEM

Disorders of the Female Reproductive Tract

The quality of the egg and its shell can be a reflection of the health of the hen and reproductive tract that produced it; consequently, veterinarians are occasionally called on to comment on abnormal eggs. A number of abnormalities have been observed (Table 41.14).

Table 41.14 | Assessment of Egg Quality

Observed Abnormality	Possible Causes
Shell too thin	Immaturity of hen Malnutrition Salpingitis causing rapid transit of egg through tract Genetics
Shell too thick	Excessive calcium supplementation
"Stress lines" – ridging and grooving of the egg shell	Salpingitis due to infection or excessive egg laying Copper deficiency
Shell texture chalky	Immaturity of hen First eggs of the season
Blood on the shell	Maiden hen Salpingitis
Excessive porosity	Immaturity of hen Start or end of laying season Nutrition Genetics
Floating air cell	Rough handling by bird or people Genetics
Cracked or damaged shells	Eggs laid while standing up Rough handling by bird or people
Abnormal shape	Salpingitis External pressure on oviduct compressing the egg as it forms eg, fluid in abdomen due to yolk-related peritonitis

Yolk-related peritonitis occurs when yolk is deposited into the abdomen rather than passing down the oviduct. The infundibulum in ostriches is a large, delicate membrane that moves up and surrounds a developing ovum. Any inflammation of the oviduct or infundibulum can result in this process not proceeding normally, and the ovum fails to enter the oviduct. Alternatively, the ovum does enter the oviduct, but retropulsion pushes it cranially and out through the infundibulum. The yolk constituting the ovum provokes a peritoneal inflammatory response, producing large volumes of fluid as a result. Affected hens usually have a history of having been good layers that suddenly stop laying eggs or may produce abnormally shaped eggs. Examination shows distension of the abdomen and a flaccid, enlarged vent. A fluid wave can be balloted on cloacal examination, and ultrasound can detect the fluid accumulation. Hematology reflects a marked leukocytosis. Abdominocentesis, performed with an appropriate catheter (eg, 14 ga in an ostrich) on the flank behind the last rib, reveals a yellowish pink fluid. Early or mild cases may respond to antibiotic and anti-inflammatory therapy, but severe cases may require a flank laparotomy to allow drainage of the fluid and lavage to remove yolk material.

Salpingitis can be due to infection (ascending or descending) or bruising following excessive or difficult egg laying. The bird may show any or all of the following signs: cessation of egg production, cloacal discharge, stress lines on eggs (Fig 41.24), increased embryonic mortality, or signs of ill health. Physical examination and laboratory work-up other than a leukocytosis may be unrewarding. Ultrasonography may reveal caseous mate-

Fig 41.24 | Stress lines in an ostrich egg from a hen with salpingitis.

Fig 41.25 | Prolapsed phallus, mature ostrich cock.

rial and fluid within the oviduct, and an oviduct swab may detect the presence of infection and/or inflammation. Antibiotic therapy should be based on culture and sensitivity, and cases with caseous exudate in the oviduct may require the surgical insertion of a Foley catheter into the magnum or isthmus, followed by normograde flushing to expel debris from the oviduct.³³

Two ostriches with caseous salpingitis were treated with dinoprost tromethamine, a prostaglandin PGF₂₀ salt.d In both cases, the hens were treated with one 5-mg injection. This was followed within 15 minutes by signs of abdominal discomfort (grunting, straining to urinate and defecate, and restlessness), which lasted for approximately 1 hour. Systemic antibiotic therapy was started and given for 1 week after the prostaglandin. Follow-up ultrasonography 48 hours after the prostaglandin showed that the caseous material within the oviduct had gone, and both hens went on to breed successfully within 6 months (Doneley, personal observation). Although this treatment caused considerable discomfort to the patients, with further investigation it may prove to be a viable alternative to surgery. Ed Note: Try PGE_{lor2} either applied to cervix or injected into the oviduct to reduce pain and dilate the cervix. This probably is a more expensive therapy then owners would prefer, but it is a more bumane therapy.

Egg binding is uncommon in ratites, or at least uncommonly diagnosed. With the exception of the kiwi, the size of ratite eggs relative to body size is quite small, so the clinical signs associated with egg binding in other species are not seen in ratites. The only clinical sign may be cessation of egg laying. In smaller ratites, the egg may be palpable in the abdomen, but in larger ratites (or cases where the diagnosis is uncertain), ultrasound is usually diagnostic. Conservative treatment with oxytocin and calcium may resolve some cases, but surgery may be required.

Although uncommon, prolapse of a large portion of the oviduct of mature egg-producing hens can occur. The prognosis for these hens is generally very poor. Treatment must be instigated as soon as possible after the prolapse and requires general anesthesia and careful replacement of the oviduct, followed by a purse-string suture. If the oviduct has been prolapsed for a significant time, tissue viability often is compromised. Antibiotics and anti-inflammatory drugs are given postoperatively. An ultrasound examination is strongly recommended to detect the possibility of the presence of egg retention or other oviduct pathology (Black, personal communication).

In contrast to oviductal prolapses, an apparent cloacal prolapse is seen in immature ostrich hens aged 12 to 20 months before egg production begins. The immature oviduct secretes an albumen-like fluid as it matures. This normally drains freely into the cloaca and is occasionally noticed by observant farmers. In some birds, a persistent membrane covers the opening of the oviduct into the urodeum. This prevents the fluid from draining. As pressure builds up behind this membrane, a balloon-like structure arising from the urodeum forms and eventually bulges out through the vent, appearing as a prolapse 5 to 10 cm in diameter. Once the diagnosis is confirmed by cloacal examination, the membrane can be incised with a scalpel and the newly created opening widened manually. This allows the fluid in the oviduct to drain and the problem resolves. Prophylactic antibiotic coverage is at the clinician's discretion.

Disorders of the Male Reproductive Tract

Phallic prolapse can occur in both immature and mature birds (Fig 41.25). Immature birds attempting to mate inappropriately can damage the phallus, leading to a prolapse. As well as the treatment described below, these birds need to be isolated from other birds to allow them time to sexually mature. Mature birds can develop

a phallic prolapse following trauma or infection of the phallus and its surrounding structures or because of excessive sexual activity. Occasionally, an unhealthy bird will develop a prolapse due to generalized weakness.

Purse-string suture techniques should be a treatment of last resort in these birds. If the phallus is not traumatized or becoming desiccated, conservative treatment is usually sufficient. Isolation and sexual rest, combined with lubrication and frequent replacement of the phallus into the cloaca, may be sufficient. Anti-inflammatory and antibiotic therapy may be useful adjuncts. If the phallus is suffering significant trauma or drying out, a temporary purse-string suture combined with anti-inflammatory and antibiotic therapy may be required.

Infertility

The consistent production of infertile ("clear") eggs requires a thorough veterinary investigation. Before beginning such an investigation, it is vital to review records and procedures. All eggs that fail to develop or hatch should be necropsied as described earlier. Numerous cases of assumed infertility have subsequently been shown to be early, or even mid-term, embryonic deaths.

Possible causes for true infertility include the following:

- Incompatibility: Some birds simply are not compatible
 and will not mate. Occasionally, if birds are run as
 trios or in colonies, a dominant hen may prevent mating with other hens by driving them away from the
 cock.
- Immoturity: Many farmers have unrealistic expectations
 of when they can expect their birds to perform. As
 hens generally mature earlier than cocks, egg production may occur before the cocks are physically capable
 of mating.
- Environmental disturbance: If birds are feeling threatened by disturbances in their immediate environment (such as construction work, traffic, dogs), they may show little interest in mating. The presence of another cock bird in the adjoining enclosure may trigger territorial behavior and inhibit mating.
- Nutrition: Excessively fat or excessively thin birds often show little interest in mating. Imbalances in vitamin and mineral content of the diet may cause decreased spermatogenesis.
- Poor health: Sick or injured birds may not mate.
- Time of season: As most ratites are seasonal breeders and the hens come into breeding condition before the cocks, the first few eggs of a breeding season may be infertile.
- True male infertility: This is uncommon and can be assessed by semen collection and evaluation.

MISCELLANEOUS DISEASES

Erysipelas is occasionally diagnosed in emus in Australia and the United States. *E. rhusiopathiae* is transmitted by ingestion of contaminated soil and through skin lacerations. Typically, affected birds die with few clinical signs other than a short period of depression. Necropsy shows hepatomegaly, splenomegaly and petechial hemorrhage on serosal surfaces of the viscera. Culture of *E. rhusiopathiae* from the liver, spleen or heart blood is diagnostic. Affected birds can be treated with penicillin or quinolone antibiotics. The turkey vaccine can be used in susceptible birds at 6 weeks, 20 weeks and 40 weeks.⁵⁸

Salmonellosis has been reported in ostriches, emus, kiwis and rheas. *Salmonella pullorum, S. typhimurium* and *S. arizonae* have been isolated, with both vertical and horizontal transmission possible. Carrier birds, rodents, freeliving birds and mammals can act as reservoirs for the infection. Clinical signs can include embryonic and neonatal mortality, and depression, diarrhea and sudden death in juvenile and adult birds. Antibiotic therapy (eg, quinolones) can suppress clinical signs but may create chronic carriers. Good biosecurity measures are necessary to both prevent infection and to limit its spread.⁵⁸

Anthrax, caused by *Bacillus anthracis*, has been diagnosed in ostriches in South Africa. Spores lying dormant in the soil for many years act as the reservoir for infection. Death occurs acutely with few clinical signs. Demonstration of the characteristic organism in blood smears is diagnostic. There is no recommended treatment. Carcasses should be disposed of by incineration (*Editors Note: Burned Spores are liberated and this may not be an ideal practice*) or deep burial. An inactivated vaccine is available.⁵⁸

A necrotizing typhlitis, associated with a mixed spirochete and trichomonad-like protozoan, has been reported in rheas. Juveniles older than 1 month are susceptible, with affected birds showing depression and anorexia. The mortality rate may exceed 50%. Necropsy shows distension and hyperemia of the ceca and colon, with fibronecrotic and pseudomembranous changes. Oral metronidazole and parenteral lincomycin reduce mortality in affected flocks.

Plasmodium spp. have been reported in ostriches in Africa, in rheas in Brazil and in emus in North America. *Leukocytozoon* spp. are considered common in juvenile ostriches in South Africa.³⁴ An as-yet-unidentified *Babesia* sp. has been isolated from North Island brown kiwis in New Zealand and is considered common in wild populations. A *Hepatozoon* sp. also has been recovered from the same birds.^{38,50} Affected birds of all species show weakness and weight loss, with a regenerative anemia. Treatment of

avian malaria is discussed in other textbooks.

Aegyptianella pullorum, a rickettsia, is transmitted by argasid ticks in Africa and causes anemia, pyrexia and death in ostrich chicks. Diagnosis is by detection of the organism in erythrocytes. Treatment with tetracyclines is usually curative.³⁴

Anesthesia and Surgery of Ratites

The size and potential danger of many ratites present unique challenges to the avian anesthetist. An anesthetic regime must offer a quick, safe and minimally stressful induction, consistent maintenance and a rapid recovery, while at the same time minimizing the exposure of the operator to risk of injury from the patient. To these ends, a number of anesthetic regimes have been devised.

Masking with isoflurane at 5% at oxygen flow rates of 2 to 4 liters per minute can usually safely and easily induce ratites weighing less than 15 to 20 kg. Once induced the bird can be intubated and maintained on 2 to 3% isoflurane at 1 to 2 liters per minute. Assisted ventilation may be advantageous in longer procedures. Recovery is usually rapid, and the bird should be manually restrained or wrapped in a towel until fully conscious.

Larger ratites will require injectable induction, followed by intubation and gaseous maintenance. The following are some suggested protocols:

- Sedation with intramuscular azaperone (0.5-2.0 mg/kg), followed 10 to 15 minutes later with an intravenous combination of ketamine (8-10 mg/kg) and diazepam (0.2-0.4 mg/kg), mixed in the same syringe and given as a bolus⁵
- Tiletamine-zolazepam (2-8 mg/kg) intravenously⁵¹
- Alphaxalone/alphadolone (2.2-4.8 mg/kg) intravenously⁵¹
- Ketamine (5 mg/kg IM or 2.2 mg/kg IV) plus xylazine (1 mg/kg IM or 0.25 mg/kg IV)²⁰
- Medetomidine (0.26-0.54 mg/kg IM) has been used in cassowaries for sedation and restraint,⁷⁰ and at 0.1 mg/kg for sedation of ostriches²⁰

It is important when anesthetizing large ratites to ensure that adequate padding is placed under the pelvis and femur to avoid peroneal paralysis. If possible, the bird should be positioned in sternal recumbency to assist ventilation. If lateral or dorsal recumbency is necessary, assisted ventilation will be required at a rate of 6 to 12 breaths per minute. The expandable pouch in the trachea of emus must be bandaged during this procedure.

Analgesia and intravenous fluid administration will contribute toward a smooth course of anesthesia. Opioids such as butorphanol or NSAIDs, such as flunixin, carprofen and meloxicam, have been used in ratites. Care should be taken to avoid both hypothermia and hyperthermia, and regular assessment of cloacal temperature is useful in long procedures.

For anesthetic recovery, the bird should be placed into sternal recumbency. This is a potentially dangerous time for the patient. Birds startled by loud noises or other stimuli may rear up and fall over backward, causing themselves injury and even killing themselves. For this reason they should be placed in a quiet, dark area and movement kept to a minimum. Placing them in a crate or horse trailer or surrounding them with hay bales can prevent them from rolling into lateral recumbency. Ostriches should be hooded, and remain hooded, until they can hold their heads upright unaided.

ABDOMINAL SURGERIES⁵

Chicks

Most laparotomies in small ostrich chicks are performed with the bird in dorsal recumbency.

The approach for yolk sac surgery or exploration of the abdominal cavity is via a ventral midline incision. In yolk sac excisional surgery, an elliptical incision incorporating the umbilicus is utilized. Immediately below the skin is an extremely thin abdominal lining. This lining consists of a connective tissue layer with a black-pigmented peritoneum immediately below. Care should be taken in incising these layers, as the dilated volk sac can be very close or even adhered to the peritoneum. Once the abdomen is exposed, the incision may have to be lengthened to enable the yolk sac to be exteriorized. Again, care must be taken as the yolk sac may rupture if excessive pressure is applied to it. The vitelline duct and blood vessels are ligated between the yolk sac and duodenum, and the yolk sac is removed. The abdomen can be irrigated using a warmed saline solution, and a small amount of aqueous antibiotic can be infused (eg, amoxicillin or ampicillin). This is particularly important if the yolk sac has been ruptured either before or during the surgery. Occasionally the volk sac may be very inflamed and adhered to the abdominal wall or intestine. Careful dissection is necessary to remove all yolk sac tissue without significant damage to the intestinal serosa. The abdominal incision is closed in two layers: muscle and skin.

A proventriculotomy is performed via an incision over the proventriculus on the left ventral abdomen. This incision normally is sited within the left abdominal pterylae. If the incision is properly sited, the surgical area is isolated from the rest of the abdomen by fascia and air sac lining, and suturing of the proventriculus to the abdominal wall is unnecessary. If the incision is positioned too far back toward the posterior abdomen, the intestines can be directly visualized and accessed. This area should then be closed by suturing before the proventriculus is entered to avoid contamination of the abdomen by spillage of proventricular contents. The relatively thin proventricular wall is located just below the thin ventral abdominal wall. The proventriculus and the ventriculus can both be accessed via this approach.

The ventriculus should be approached via a proventriculotomy rather than directly incising the ventriculus. Any free fluid in the proventriculus can be aspirated and then the impacting material or foreign bodies can be removed. The closure is in three layers: proventriculus, abdominal wall and skin. The proventricular closure is achieved using a continuous Lembert-type suture pattern using absorbable synthetic suture material. The abdominal wall is closed with similar suture material. The skin closure can be done with absorbable or non-absorbable material.

Older Chicks and Adults

Abdominal surgery on older ostrich chicks and adults is usually performed with the birds in lateral recumbency, lying on their right side.

Entry into the abdominal cavity is via an incision through the left abdominal wall in the flank apterylae. The position and orientation of this incision will be determined by the nature of the condition leading to the laparotomy. For example, most egg yolk peritonitis surgeries are performed via a vertical incision about halfway between the back of the left thigh and the posterior margin of the abdomen. In some instances, a horizontal incision may be used (eg, to gain greater oviduct exposure), or even a T-type incision combining both can be used. The horizontal incision usually results in greater hemorrhage and is subjected to much greater tension on closure. The skin is incised to reveal two muscle/fascial layers directly below (there is very little subcutaneous tissue). Between the second muscle/fascial layer and the peritoneum is a variable and sometimes excessive fat layer. The peritoneum is opened by puncture using blunt-pointed scissors. The peritoneum is pigmented (gray color of varying darkness) and very tough.

With yolk-related peritonitis, significant yolk-stained fluid can be present in the abdomen. This fluid will immediately begin draining through the surgical opening, often under pressure because of the bird's positioning. This fluid can be aspirated or allowed to passively drain. Tilting the bird's abdomen downward facilitates

drainage. The abdomen can be manually explored to detect the presence of inspissated yolks, retained eggs or neoplasia. The aim of the surgery is to extensively flush the abdomen until all yolk debris has been removed. This can be a very difficult exercise in view of the size of the abdomen, the length of intestine present and the relatively difficult access. The abdomen is flushed with 0.25% Betadine in saline until no further debris is found and the fluid escaping the abdomen becomes clear. This can take up to 12 to 14 liters of fluid. A final liter of saline and antibiotic is instilled into the abdomen, and 250 ml of this solution is usually infused into the oviduct lumen via a needle through the anterior oviduct.

The oviduct is visualized to detect any pathology such as edema, inflammation or neoplasia. The entire length is palpated to detect any blockages or retained eggs. The infundibulum also is visually inspected. It is imperative to avoid much handling of the infundibulum. This is a highly motile, thin and delicate structure, which is easily torn, bruised or inflamed. It is also important to ensure that the infundibulum is kept well away from the incision site during suturing of the peritoneum.

The closure of the abdomen is normally done in four or five layers. The peritoneum is closed with synthetic absorbable suture in a simple continuous pattern. The two muscle/fascial layers are then closed either separately or as one layer using similar material. A subcutaneous suture may then be done using a lighter absorbable suture. The skin is usually closed with non-absorbable suture. This skin closure is an interrupted pattern of simple or mattress sutures.

The prognosis associated with this procedure is influenced by the length of time the condition has been present and the degree of damage found in the abdomen. Prognosis for survival is excellent, but prognosis for future productivity is guarded, with expected success rates, with experience, of about 66%.

Severe salpingitis cases may best be treated surgically. An intrauterine infusion of an appropriate antibiotic saline solution is employed via a needle or Foley catheter introduced into the proximal oviduct (magnum). A volume of 250 to 1000 ml is used, depending on the extent and nature of the infection. Care must be taken to avoid retrograde passage of fluid back into the abdomen via the infundibulum.

Some retained eggs may be accessed via the cloaca and removed manually while the bird is anesthetized. Eggs higher in the oviduct can be removed only surgically. The site of the retention can be previously ascertained by an ultrasound examination. Access to the lower oviduct is difficult. The oviduct is very friable and has

poor suture-holding properties. After egg removal from the incised oviduct, the wall is sutured carefully using synthetic absorbable suture material in a continuous Lembert-type pattern.

Proventriculotomy surgery in older birds is done in a fashion similar to that of chicks with the amount of abdominal fat being the major difference. It is not uncommon to encounter up to 15 cm of abdominal fat during the surgical approach. This makes access limited in some cases and creates some difficulty for easy suturing.

Occasionally, a decision may be made to perform the laparotomy with the bird in dorsal recumbency and the incision made on the ventral abdomen. This is rarely done, but may be required to access some intestinal problems (especially those involving the small intestine). In these cases, it is necessary to slightly extend the legs to avoid potential nerve and muscle injury at the level of the upper thigh during the procedure.

Intestinal volvulus is not uncommon in ostriches and is especially associated with diet changes. Some cases will occur without any obvious predisposing trigger. Gutpenetrating injuries also can occur after ingestion of sharp objects such as sticks, nails and wire. Diagnosis is based on clinical signs (anorexia, depression, abdominal pain, lack of fecal passage), abdominal paracentesis, hematology and possible radiology. Ostriches appear to have very little tolerance to musculoskeletal pain, but show remarkable tolerance to visceral and abdominal pain. It is possible that birds with significant peritonitis and avascular necrosis of a section of gut may show only mild symptoms of abdominal pain.

The laparotomy site is usually the left lateral abdomen, as described previously. A decision to access the abdomen via a midline approach may be made if the problem is suspected in the upper small intestine or if there is insufficient access via the lateral route. If nonviable intestine is found requiring resection and anastomosis, a poor prognosis should be given. The large intestinal wall is extremely thin and very difficult to suture successfully. Peritoneal lavage using saline and a saline/antibiotic solution is necessary in all cases, as invariably a septic peritonitis is present. If surgical intervention is early enough, it is possible to correct a volvulus or intussusception without further complications, provided gut viability is present.

Postoperative Care

Apart from cases of yolk sac excision or egg yolk peritonitis, most laparotomy cases in ostriches do not require intensive postoperative care.

Chicks recovering from yolk sac excisional surgery require

close monitoring, heat support and frequent tube feeding. The tube feeding may be necessary for only 24 hours or may be required for several days until the chick becomes self-sufficient and is regularly gaining weight.

Most laparotomy cases require immediate postoperative antibiotics. The final choice of antibiotics will be determined by any culture/sensitivity testing previously carried out. Tube feeding in some chicks also may be required during the postoperative period. Suture removal, if necessary, is done at a minimum of 2 weeks after surgery.

SKIN LACERATIONS

Generally, lacerations of the skin of the neck, body and upper thighs heal very well once sutured. Some neck lacerations may heal well with minimal intervention. Lower limb wounds are less rewarding due to tension and secondary infection. If possible, administration of general anesthesia to recently traumatized birds is avoided. Local anesthesia, if possible, is safer. If the trauma is too severe for the use of local anesthesia, it is preferable to determine the status of the bird by blood sampling and evaluating the full blood examination and biochemistry profile. This should be combined with immediate stabilization of the patient using intravenous fluids, analgesics, and antibiotics.

Traumatic penetrating wounds to joints and tendon sheaths should be treated vigorously using local and systemic antibiotics. If infection is suspected, culture and sensitivity testing is essential. Joint lavage will be necessary if fistulae and significant joint infection are already present.

ORTHOPEDICS

The likelihood of the veterinary surgeon being requested to perform orthopedic procedures on ostriches is now quite low. Severe leg fractures or luxations usually result in a decision to euthanize the bird. Most cases of beak trauma can be handled medically. It is quite surprising to see ostriches suffer very little setback, even with major beak trauma resulting in significant defects. Wing fractures will commonly repair after simple taping of the wing back into correct position. This is best achieved by taping wing feathers to body feathers at several sites. This avoids the stress of complete body wrap taping of wings. Severe wing fractures can be handled by amputation if necessary.

EYES

Surgical repair of eyelid lacerations is common and usually rewarding.

Eyelid closure to treat corneal ulcers and keratitis can be

performed as described in many textbooks, and may even be done using local anesthesia. The strength of the eyelid muscles is surprising and requires the placement of quite heavy-gauge suture material.

Enucleation can be performed in chicks. In adults this is a difficult procedure with significant risk of hemorrhage. Adult hens have been reported to not breed following unilateral enucleation. This is not always the case, as some birds, apparently in severe pain prior to enucleation, have bred successfully within weeks of the surgery.

Cataract removal using phacoemulsification techniques has been carried out in Australia and the United States (Fig 41.26). This is becoming less common now that bird values have reduced.

Periorbital abscessation resulting from bacterial sinusitis is relatively common in ostrich chicks. These tend to result in discrete swellings on the skull in a dorsomedial position relative to the eye. After local anesthesia, an incision can be made into this swelling to enable debridement and excision of firm gelatinous-like pus. Local irrigation with appropriate antibiotics combined with systemic antibiotic therapy after culture and sensitivity testing are needed to effect a normally uneventful recovery.

Acknowledgements

I thank the following people for their invaluable contributions to this work. Doug Black (Ostrich Health Consultant, Moama, New South Wales) gave me valuable

Management of

Zoo and Park Birds

LORENZO CROSTA, DVM, LINDA TIMOSSI, DVM; MARCELLUS BÜRKLE, DVM

The role of the veterinary staff in a zoological setting involves the active promotion of animal health and well being in addition to the treatment of overt diseases. It is uncommon for a zoo veterinarian to be involved strictly in avian medicine, although this may occur when a veterinarian is employed in a zoological garden that is a bird park. More commonly, an avian veterinarian will be consulted when problems with avian species are encountered in a mixed species zoologic collection.

The Purposes of a Zoo or Bird Park

A zoological garden or bird park, whether private or open to the public, is a place where animals (birds) are exhibited. One of the most important concerns of the zoo is the appearance of the displayed animals. Zoos are constantly under pressure from animal rights activists. In many countries, including the USA, zoological gardens have legal requirements, including animal welfare rules and legislation, to which they must adhere.

Additional purposes or goals of zoologic parks include:

- Maintenance of the genetic pool of selected species.
- Geographically orienting management and exhibition of animals according to their natural distribution (eg, South American birds located contiguously).
- Gaining biologic and ecologic information regarding the applicable species.
- Performing specific research projects in areas of nutrition, behavior, genetics and disease.

Routine Zoo Veterinary Work

The veterinarian's work in a zoo involves adherence to strict protocols including meticulous record keeping. A thorough understanding of the concepts and challenges of aviculture is required. Management, husbandry and medical and surgical protocols must be developed and performed (Table 42.1).

Medical Equipment

Zoo veterinary equipment for the avian collection does not differ significantly from that encountered in a normal exotic animal clinic (Table 42.2). Its availability will depend on budget and ease of outside sourcing. Housing for hospitalized birds is outlined in Table 42.3.

Depending on local veterinary support, the zoo veterinary clinic may need a full range of surgical and diagnostic tools including microbiology, hematology, blood

Table 42.1 | Recommended Veterinary Routines for Zoo and Park Birds

Daily

Evaluate hospitalized patients

Review laboratory results received

Develop or alter treatment based on the above

Examine nursery birds, park exhibits and breeding birds, making appropriate notes, examining individuals, obtaining samples and retrieving birds for hospitalization as needed

Perform any required surgeries

Weekly

Interdepartmental meetings to review schedules and plans for routine procedures

Monthly

Routine deworming and fecal examinations

Vaccinations as appropriate

Yearly

Annual physical examination of every animal in the park; plan further testing, if warranted Evaluate unsuccessful breeding pairs

Table 42.2 | Recommended Medical Equipment for Zoo and Park Birds

Endoscopy

Both rigid (standard avian) and flexible (larger bird) endoscopes of various diameters

Surgery

Standard surgical equipment and facilities for exotics Anesthesia

A portable anesthesia machine for larger patients such as ratites

Radiology

A portable x-ray machine is often needed in a zoo Ultrasound

A portable ultrasound machine equipped with various sized probes

Cages, hospital cages and aviaries

A variety of enclosures for various avian patients is desirable (see Table 42.3)

chemistry and cytology, histopathology, toxicology, virology and special tests, some which may be submitted to outside laboratories.

The Importance of Biology and Taxonomy

Recent discoveries in zoology, field biology, morphology, ethology and DNA-based genetics need to be monitored and, where appropriate, implemented into the medical protocols. Understanding these issues allows the zoo veterinarian to form an idea about the correct husbandry conditions (eg, environment, temperature, diet) to provide. Taxonomy of a closely related species for which good medical information is available will be invaluable in the approach to any novel species.

Table 42.3 | Recommended Cages for Different **Avian Patients**

Avian Patient	Recommended Cage
Critically ill birds	They need a warmed cage, ideally an Intensive Care Unit (ICU). This applies to any avian patient in critical condition. The hospital cage should be connected to an O ₂ delivery system, with the temperature and humidity controlled.
Potential infectious patients	A zoo must have a special area for animals that may carry an infectious disease. This area should be separate from the quarantine for incoming birds.
Psittacines	See Chapter 7, Emergency and Critical Care.
Birds of prey (diurnal and nocturnal)	See Chapter 40, Management of Raptors.
Cranes, storks and flamingos	Although these animals have totally different feeding habits, they have similar hospital needs. Flooring must provide adequate traction. Hard rubber mats are ideal since they can be disinfected. Flamingos must be housed with access to the water and food blend that they consume via filtration through their beaks.
Small passerines	Some species may be very shy and easily stressed, so English-style cages (with 3 solid walls) are preferred.
Ratites	See Chapter 41, Management of Captive Ratites.
Penguins and auks	Penguins belong to the Order Sphenisciformes. There are 17 living species of penguins, divided into 6 genera. All penguin species live in the southern hemisphere. The term "auk" includes species of the Alcidae family, 21 species in the world, which include the guillemot, or murre (Uria aalge), razorbill (Alca torda) and puffin (Fratercula artica). Penguin and auk species require species-specific environments, but they all need to swim, preferably in a relatively cold saltwater pool. If a zoo includes penguins and/or auks among its species, an appropriate area should be built for quarantine and hospitalization room(s). An ideal room for nursing these aquatic birds meets the following requirements: 1. A saltwater pool within easy access of the birds. 2. Environmental air and water temperatures cooled to 0° C (32° F). 3. Water and air filtration systems (to decrease the potential for aspergillosis).
Anseriformes	See Chapter 36, Management of Waterfowl.
Galliformes	See Chapter 38, Management of Galliformes.
Columbiformes	Pigeons and doves, like the two preceding groups, vary in size, husbandry and dietary requirements. For short-term nursing, they can be kept in cages similar to ones for psittacines or birds of prey. Some of the shyest of the species (ie, the large crowned pigeons [Goura spp.]) should be kept in a very quiet environment (see Chapter 37, Management of Racing Pigeons).

Fig 42.1 | Cooperation with the gardeners helps achieve pleasant looking cages, while avoiding toxic plants.

Fig 42.2 | Some bird species, such as these rockhopper penguins (*Eudyptes crestatus*), have extreme temperature and humidity requirements.

The Importance of Teamwork

A common problem encountered during setup of a new exhibit or refurbishing an existing one is the lack of team work. Often the architects, biologists, curators, keepers and veterinarians have different perspectives on what the ideal exhibit should be for a given species, but all these points of view must be collated before the building or refurbishing work begins. The basic issues of an exhibit design should be addressed in the preplanning phase. Once the building work has started, it is often impossible or too expensive to make changes.

Experienced, committed keepers understand the behavior and personalities of the animals. They know the daily cleaning and feeding routines and can offer important suggestions about materials best suited for furniture, fencing, drainage and access to aviaries. Keepers who work with aggressive birds (eg, ratites and large cranes) can be helpful in developing solutions for their safe transport from the exhibit to holding areas.

The veterinarians and gardeners, or horticultural department if there is one, are involved in the selection and control of the vegetation to be planted, thereby eliminating the use of toxic plant species inside the exhibit (Fig 42.1).

Additionally, keepers' suggestions are invaluable when planning service areas and pest control.

HOUSING

Housing is one of the most important aspects of keeping birds in a zoo. In an up-to-date setting, animals must not only be healthy but also be exhibited in the most "natural" environment possible.

Temperature and Humidity

Most commonly kept zoo and park birds do well in the

average temperate climate, but exceptions do exist. Most tropical birds, especially smaller ones, need temperature-controlled housing for winter, in addition to warm spots, even during summer nights. There also are birds that need some accessible areas away from extreme heat to thrive during the summer months (Fig 42.2). Some of these species are easily identified (eg, penguins, snowy owls, gyrfalcons). Bird species that are represented in different climates by multiple subspecies, such as the peregrine falcon (*Falco peregrinus*) or the osprey (*Pandion baliaetus*), offer special challenges. It is better to obtain a local subspecies in order to avoid stress due to inappropriate climate.

Light Cycles

Most bird species are highly dependent on photoperiod for their reproductive cycle, but other physiological issues (eg, molting) also are light-cycle dependent. This is important for birds originating from the extreme northern or southern latitudes and must be taken into consideration when designing an exhibit for these species.

Flooring

Flooring is of primary importance in a birdhouse (Figs 42.3-42.5). When approaching bird management, the avian veterinarian must keep in mind two important things:

- Avian species have evolved with multiple anatomic and functional variations of the feet (eg, webbing, talons, feet for wading), which require the appropriate caging materials in captivity.
- Birds are bipedal; therefore, damage to one foot places 100% of the weight-bearing load on the remaining contralateral foot. For all but the smaller species, this increased load and decreased mobility can quickly lead to affliction of the plantar surface of the remaining foot.

Fig 42.3 | Natural flooring and a proper diet promote healthy feet, as in these demoiselle cranes (*Grus* [Anthropoides] virgo).

Fig 42.5 | Aquatic species, such as these little blue penguins (*Eudyptula minor*), need a proper pool to allow swimming and prevent foot problems.

Roofing

Some non-flying species (eg, ratites) do not need a roof. Also, some birds have limited ability to fly because they have been pinioned or their wings are regularly trimmed. This often applies to ducks, geese, swans, flamingos and sometimes cranes and storks. When a roof is designed, several factors are taken into consideration.

It is important to know if the birds will or will not be on exhibit. If so, the roof will have to be both effective and have a natural look. "Invisible" nets are available and work well in these cases. Because some species may bite and chew on the roof, this should be considered when selecting roofing material.

Another factor is the ability of a species to climb and become trapped in a mesh roof. Roofing for birds of prey and other birds that might become trapped in mesh can be made with wooden lathing strips, 2 cm thick and 10 cm wide. The strips are arranged horizontally, 5 cm apart, allowing resting birds to see the sky and receive fresh air, rain and snow, if advisable; when the birds are flying, this roof will appear as a solid wall

Fig 42.4 | Natural displays should include the different plants that occur in a bird's natural habitat. Marsh owl (*Asio capensis*) shown.

and the birds will not fly into it (Figs 42.6a,b).

Vegetation

Most bird species like plants and branches in their aviaries for hiding, perching and nesting, but not all trees are appropriate for planting. Normally, large zoos employ botanists or experienced gardeners who can help veterinarians and curators select local plants suitable for installation in large aviaries or exhibits.

Perches

Perches, whether provided alone or in conjunction with planted trees, must offer a good base for both rest and exercise. Ideally, perches should provide a variety of textures, diameters and elasticities. When perches are made of a variety of different materials, sizes and shapes, they will provide the birds' feet with exercise, equal weight distribution and natural nail trimming (Figs 42.7a-c).

Food and Water Delivery Systems

In most bird collections, food and water are provided twice daily. During the summer and year long in warm climates, food and water easily become polluted by bacteria, fungi and protozoa and can be the source of serious health problems. Feeding schedules and equipment must be adjusted according to the type of food (eg, seeds, dry, wet, fish, live food) used for the different bird species. In general, hygiene is the most important issue. Food and water bowls must be changed daily, and good cleaning and disinfection procedures are necessary to avoid spreading pathogens from one enclosure to another.

Figs 42.6 a,b | A properly designed roof for flying birds (ie, birds of prey) will appear to the birds as open air or solid, depending on perspective.

Fig 42.7 | A selection of branches and other natural perches to exercise the feet is a must in exhibits for wild species. a) Great grey owl (Strix nebulosa). b) Red-tailed black cockatoo (Calyptorhynchus banksii). c) A variety of branches in an aviary.

In some facilities, water is delivered through an automatic watering system. The system's pipes must be checked on a regular basis for hydrophilic bacteria, especially *Pseudomonas* sp. Cleaning and disinfecting the pipes should take place on a regular basis. Natural exhibits with a lake or waterfall as the main source of the birds' water intake should have a high-quality filtration system. Weekly bacteriologic and chemical tests (eg, nitrogen and chlorine) should be performed using one of the available commercial kits. Using a dipping media for urine bacteriology allows identification of type and number of bacteria in the water.

Nests

For many species, nests are necessary for reproduction and may be a stimulus for breeding activity. Although some exceptions do occur (eg, macaw and cockatiel), most psittacines will not breed without a nest box.

Searching for a nest site and building a nest can play important roles in mating behavior and breeding success. Less commonly, species like king penguins (*Aptenodytes patagonica*) do not build nests but incubate their single-egg clutches on their feet, which are covered by a skin fold. Even these birds need to be provided with an adequate breeding area where they are protected against weather and feel safe from actual or perceived threats, such as predators.

Choosing the best nest sites and adequate nest shapes for different types of birds falls to the biologists and curators, but the veterinarian's medical input should be included in the decision-making process (Figs 42.8, 42.9).

Nest Hygiene

Depending on the species, nests can easily become dirty with excrement from the offspring. Parasites and bacteria proliferate in this organic medium. Consequently, selection of bedding material is important. In general, bedding material should be clean and free of pathogens. Inadequate bedding material has been reported as a cause of aspergillosis in neonatal parrots and other avian

Fig 42.8 | Nest sites should meet species-specific needs. A diamond dove (Geopelia cuneata) is shown.

Fig 42.10 | A nest box for lories, built using wire mesh for the floor, allows the liquid feces to drop and ensures better ventilation.

species. Ectoparasites can be avoided by adding 5% carbaryl powder to the bedding material at the beginning of the breeding season. Bedding material should be routinely tested for bacterial and fungal contamination. Toxic substances also can cause problems in this respect. Wood shavings, widely used as nest bedding, must exclude the presence of paints, resins and wood preservatives.

The condition of the bedding material must be monitored during the breeding season. This should be undertaken in cooperation with the curator or animal keeper in order to not disturb the breeding pair. In some species, like lories and lorikeets that feed on a liquidbased diet resulting in voluminous stools, it may be necessary to change or add new bedding material during egg incubation or while the young are still in the nest. For these birds, a specially designed nest box has proven to be effective against pollution. Instead of a wooden floor, the nest box is built using wire mesh, allowing the liquid feces to drop through and ensuring better ventilation (Fig 42.10).

Cleaning and disinfecting the nest after the breeding season should be carried out carefully. Wooden nest boxes may require replacement. Natural trunks should

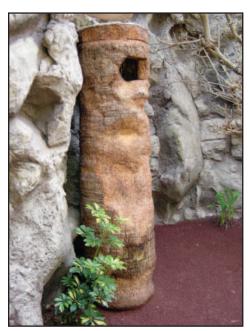

Fig 42.9 | Empty trunks can be used as nests for selected species. Shown is a palm trunk nest provided to Pesquet's parrots (Psittrichas fulgidus).

be cleaned as carefully as possible, and appropriate disinfecting solutions, which allow the birds to use the nesting site again, should be used. In species like the gentoo penguin (Pygoscelis papua), which uses stones for nesting, the stones should be removed and carefully cleaned after the breeding season. Permanent nesting sites, eg, caves for puffins (Fratercula arctica) or other cave-breeding species, must be designed for ease of cleaning and disinfecting. The design of a nest should be a compromise between the natural breeding behavior of the species, its specific hygiene requirements and the captive situation (Figs 42.11a,b).

Controlling the Nest Site

Nests should be designed in a way that allows evaluation of parents, eggs and chicks (Fig 42.12). In case of irregularities in the behavior of the parents, evaluating and/or removing the offspring may be necessary.

Risks to the Offspring

Leaving the nest for the first time after weaning is a risky situation for young birds, and fractures or other traumatic injuries can occur. Therefore, nests should be designed to minimize the risk of fledglings flying into wire mesh or other dangerous structures of the cage. To help prevent such accidents, tree branches can be placed in front of the nest a few days before fledging.

DISEASES

Identification of Sick Animals

Routine controls include daily rounds during which all the aviaries and exhibits are inspected, and, if war-

Figs 42.11 a,b | In an exhibit housing cave nesters and bird species that build nests using stones, special attention to the hygiene involved in such an exhibit is required. Shown are gentoo penguins (*Pygoscelis papua*) on a nest and a pair of Humboldt penguins (*Spheniscus humboldti*) in the cave nest.

Fig 42.12 | Nests should be designed in a way that allows control of parents, eggs and chicks. A great grey owl (*Strix nebulosa*) with a 1-day-old chick is shown.

ranted, samples are collected for laboratory evaluation (see Table 42.4).

Species-specific Diseases

Viral diseases tend to be more species-specific than bacterial or fungal diseases. In parrots, one might see psittacine circovirus, avian polyomavirus or Pacheco's disease. Other viral diseases that are specific to selected bird groups and encountered in zoo settings are avian poxvirus infections and herpesvirus infections (HV).

Some HV may be extremely dangerous for flocks of sensitive species. HV are generally pathogenic for a single group of birds, but other bird families, even those not very taxonomically close, may sometimes be susceptible. For example, pigeon herpesvirus causes disease in pigeons, Arctic falcons and sometimes in owls. Typically, herpesvirus infections cause neoplastic, hemorrhagic or necrotic lesions. A group of these diseases causes necrotic hepatosplenitis in falcons, eagles, owls, cranes, storks and pigeons.

When an outbreak of disease occurs in a zoo, bird movement should be limited.

Multi-species Diseases

Most bacterial and viral infections potentially are transmittable through many avian species and orders. In this respect, an extremely strict routine for disinfection of selected areas in the zoo (eg, food preparation, chick hand-rearing station, quarantine and, of course, the hospital) is important. A good strategy for avoiding bacterial resistance to disinfectants is to rotate the use of three to four different disinfectants; at selected times, a fogger for disinfecting the most unreachable spots also can be used.

It is extremely important to know the most common interspecific diseases in order to rate the risk of cross-species transmission in case of an outbreak. Bacterial examples are *Mycobacterium avium*, *Yersinia pseudotuberculosis*, *Salmonella* spp., *Pasteurella multocida*, *Chlamydophila psittaci*, *Erysipelothrix rhusiopathiae* and *Listeria monocytogenes*.

Paramyxovirus-1(PMV-1) is distributed worldwide, and all bird species are considered susceptible to PMV-1. Influenza A viruses have been recovered from several different bird orders, including species very common in zoos and bird parks, such as Anseriformes, Galliformes, Falconiformes, Psittaciformes, Sphenisciformes and Gruiformes. It also has been recovered from some mammals.

Introduced Diseases

The introduction of new animals may lead to the introduction of unexpected diseases. The chance of introducing a disease through ectoparasites or other pests traveling with the crates, cages or boxes of newly arrived animals also must be considered; hence, it is important to institute strict quarantine measures and thorough disinfection (if

Table 42.4 | Routine "On-site" Check for Park and **Zoo Birds**

1. Behavior

Look for any behavioral changes (the bird is quieter, sleeps, is nervous, turns away from the partner).

2. Physical posture

The bird sits hunched over.

The bird sleeps standing on both feet (healthy birds usually sleep on one foot).

The bird wags tail (indicates respiratory diseases or egg retention).

The bird favors its extremities (one or both wings are hanging down slightly; the bird obviously tries not to strain one of its feet).

3. Plumage

At the first stage of a disease, birds quite often ruffle a few neck or head feathers (which also may be just a threatening posture).

4. Eyes

At the very beginning of a disease, the animal's eyes are slightly—very slightly—closed. You will have to take a very close look. At the same time, the eyes are no longer shining. Seriously ill birds may have the eyes completely closed.

5. Stool

Pay attention to the quantity, color and consistency. Increased or reduced stool quantity may indicate a disorder.

Also feces' color and consistency should be monitored.

6. Ingestion of food and water

Is the ingestion of food and water normal? Does the bird eat or drink more or less than usual?

not destruction) of crates, cages or boxes used for the importation of animals.

Zoonosis

The incidence of diseases acquired by humans from birds is low (Table 42.5). The most frequent diseases of concern are usually chlamydiosis and salmonellosis. Quarantine and strict hygiene measures are the only effective methods for avoiding bird-to-human transmission of diseases. Most zoonoses are transmitted via the fecal/oral route. Birds in contact with visitors should be tested on a regular basis for potential zoonoses, and results must be archived to prove negative test results in case of a new occurrence. Positive birds should be removed from visitor contact for security reasons and treated or euthanized as appropriate.

QUARANTINE

Quarantine guidelines have been established by the American Zoo and Aquarium Association (www.aza.org) and should be adapted to each situation. Quarantine measures include all birds that are newcomers to the collection (and those that return after being on loan to another facility or from a different exhibit). All newcomers are subjected to a minimum 6 weeks' quarantine

period. Multiple quarantine rooms of varied sizes should be available for this purpose. All quarantine rooms should have separate, low-pressure ventilation systems. After a short, 2- to 4-day period of adaptation, each bird is subjected to a thorough medical examination, which includes the procedures listed in Table 42.6.

Birds may be integrated into the collection after the quarantine period in the absence of any detectable disease or infection. Special attention should be paid to behavior and feeding of new animals in the first weeks of quarantine. Food and water should be supplied in a manner equivalent to the animals' former feeding conditions at the original facility. Changes to the food and feeding schedule should be made gradually to avoid stress to the birds. A separate keeper for the quarantined birds is preferred to avoid disease transmission. Separate clothes, boots and hand and shoe disinfection baths are critical.

COMMON SENSE NUTRITION

Working in a zoo presents the veterinarian with a variety of different species, often with very unusual or specialized diets. In most circumstances, specific commercial diets are not readily available. Hence, it is important to work jointly with other professionals such as zoologists, biologists and nutritionists in an effort to customize the most appropriate diet for a given species.

In addition to the foods manufactured specifically for psittacines, diets are also commercially available for mynah birds, canaries, small finches, pigeons, thrushes, cranes, emus, flamingos, game birds, ostriches, waterfowl, aquatic ducks and toucans. Other diets are often used according to "local traditions," "avicultural myths" and keepers' experiences, which may or may not be ideal. For best results, a veterinarian should work with a nutritionist in developing a feeding plan.

Imitation of natural nutrition can be very successful, but this may not always be possible or desirable for the following reasons:

- Some or all diet components are not available.
- Nutritional requirements in captivity are different from those in the wild.
- Some foods cannot be digested in the absence of other unknown or unavailable items.
- Birds do not recognize the offered diet as food.

If a diet for birds has to be revised, especially in cases of birds for which little accurate data are available or when birds have been fed for a long time on an alternate diet, discretion is needed. Generally speaking, if a bird flock has been fed a locally developed diet for a prolonged period, it can be assumed that the diet and general management were reasonable if the birds maintain good

Table 42.5 | Zoonotic Diseases Potentially Present in a Bird Park

Disease	Etiology
Bacterial	
Campylobacteriosis	Campylobacter jejuni
Colibacillosis	Escherichia coli
Erysipeloid	Erysipelothrix rhusiopathiae
Listeriosis	Listeria monocytogenes
Miscellaneous bacterial infections	Klebsiella spp., Pseudomonas spp., Vibrio spp.
Pasteurellosis	Pasteurella spp.
Psittacosis	Chlamydophila psittaci
Salmonellosis	Salmonella typhimurium
Tuberculosis	Mycobacterium avium, M. genavense
Yersiniosis	Yersinia pseudotuberculosis
Mycotic	
Aspergillosis	Aspergillus fumigatus
Cryptococcosis	Cryptococcus neoformans
Dermatophytosis	Trichophyton gallinae, Microsporum gypseum
Histoplasmosis	Histoplasma capsulatum
Viral	
Influenza A	Orthomyxovirus type A
Newcastle disease	Avian Paramyxovirus type 1
West Nile virus	Flavivirus

physical condition. Normal laboratory examination results, successful reproduction, good quality feathering and a normal physical examination would warrant a gradual and cautious approach to dietary alterations (see Chapter 4, Nutritional Considerations).

BEHAVIORAL CONSIDERATIONS

In zoo and bird park collections, particular attention should be given to the choice of animals occupying neighboring cages due to potential incompatibility among species or individuals and aggressive or challenging behavior during the breeding season. This is particularly true for some parrot species, such as the hawkheaded parrot (*Deroptyus accipitrinus*), which seems to be affected by the presence of other pairs of the same species. Male macaws (*Ara* spp.) are protective of their partners during the breeding season, and a neighboring male of the same species may affect the mating behavior of the pair and create a stressful situation that can compromise breeding success; males are more occupied with challenging each other than with breeding.

On the other hand, parrot families such as white cockatoos (*Cacatua* spp.) appear to benefit from the presence of conspecific birds. If they are housed to allow visual and vocal contact, they will display and call to each other, and this situation might contribute to breeding success.

Sound knowledge of the natural behavior of the species is helpful when choosing the most suitable species to be neighbors. Sometimes it is only a question of common

Table 42.6 | Recommended Medical Check-up for Birds in Quarantine

- Bacteriological analysis (cloacal, choanal, tracheal)
- Mycological analysis (cloacal, choanal, tracheal)
- Parasitological analyses (endo- and ectoparasites)
- Checking for viral infections, (eg, circovirus and polyomavirus in the case of parrots and Newcastle disease for all birds)
- Checking for Chlamydophila (test for antigens and antibodies)
- · Hematological and blood chemistry analysis
- · Other tests, depending on the species

sense when choosing neighboring birds so that one of the species is not stressed, especially in a zoo collection where birds and their natural predators are maintained. An incorrect choice can create a stressful situation for the animals and will lead, at best, to the abnormal appearance and behavior of the animals. In most circumstances, a stressed bird will soon become a sick bird as well.

MIXED SPECIES EXHIBITS

The idea of keeping different species in a mixed exhibit is common in zoos. The major challenge is to weigh the benefits and risks that a mixed exhibit can offer. It is easy, practical and economically more convenient to use one enclosure to display different species. Further, a mixed exhibit can be more attractive and educational for visitors, and a combined species exhibit can have a positive effect on the physical and mental behavior of the animals. From an educational point of view, most zoos prefer that animals belonging to the same geographical area be shown in the same mixed exhibit.

Despite these advantages, the negative points of a mixedspecies exhibit are the risk of aggression among the animals and competition for position, space and food in the exhibit itself. It is important to be knowledgeable regarding the natural environment and behavior of the species to be combined and even more important to know the temperament of the individual animal in a mixedspecies exhibit.

To successfully develop a mixed-species exhibit, specific guidelines should be followed:

- Avoid combining animals that occupy the same ecological niche because they will compete for space and food. Try to use all the space of the enclosure, combining terrestrial species with arboreal and/or aquatic species.
- Primates are always problematic to combine in mixedspecies exhibits due to their inquisitive nature and the fact that they are often aggressively territorial in captivity. Nevertheless, there are examples of birds successfully exhibited with primates. Golden lion tamarins

(*Leontopithecus rosalia*), screech owls (*Otus* spp.) and red-capped cardinals (*Paroaria* spp.) have successfully been housed together.

- Avoid housing closely related species together in order to prevent the risk of hybridization.
- Provide an abundance of items the animals may compete for: perches and branches of different sizes, feeding points, nesting areas and shadows. For example, when keeping multiple hummingbirds together, a bird can be harassed by its cage mates when there are insufficient feeders (although occasional mock fights are normal behavior in hummingbirds).
- Provide the animals with the option of hiding from others, when necessary, by offering visual barriers such as plants and rocks.
- Avoid combining species that can be antagonistic in nature.
- Combine animals of different sizes when working with animals occupying the same niche. Large species have a tendency to accept the presence of small animals. Nevertheless, the smaller species may challenge the larger if the species is of a particularly aggressive or protective nature. Aggressive species can be combined with others only in a very large exhibit.

Combining birds of different sizes requires additional consideration. For example, very small nocturnal birds of prey (eg, *Athene* spp., *Glaucidium* spp.) can be housed with some waterfowl, but particular care should be taken when combining toucans (*Ramphastidae*) with passerines or other small birds like doves, to avoid predation. Cranes, waterfowl, ibises and storks are often displayed together. Some parrots also may be kept together in walk-through aviaries. Several lory (*Loridae*) species are commonly housed together in an aviary exhibit.

For birds that have the same or similar diets, or the diet of one species represents part of the diet of another, adequate distribution of food can be accomplished by providing feeding sites accessible to only one of the species (eg, flying vs non-flying species) or providing the birds with additional feeding sites.

Some examples of successful mixed-species exhibits include:

- Bali mynah (*Leucopsar rothsbildi*) with Asian glossy starling (*Aplonis panayensis*), Prevost's squirrel (*Callosciurus prevostii*) and mouse deer (*Tragulus* spp.)
- Bali mynah with chevrotain (Tragulus napu)
- Goffin's cockatoo (Cacatua goffini) and Eleonora's cockatoo (Cacatua g. eleonora) with bettongs (Bettongia penicillata)
- Emu (*Dromaius novaehollandiae*) and cassowary (*Casuarius* spp.) with red kangaroo (*Macropus rufus*) and dama wallaby (*Macropus eugenii*)

- Crowned crane (*Balearica* spp.), marabou stork (*Leptoptilos crumeniferus*), storks (*Ciconia* spp.) and ostrich (*Struthio camelus*) with giraffe (*Giraffa camelopardis*) and antelope (*Tragelaphus* spp. and *Gazella* spp.)
- Yellow weaver (*Ploceus subaureus*), black-winged bishop (*Euplectes bordaceus*), golden-breasted starling (*Cosmopsarus regius*) and speckled pigeon (*Columba guinea*) with dik-dik (*Madoqua dirkii*).

WORKING (SHOW) BIRDS

Most zoo parks and some zoos have bird shows and/or walk-through aviaries, putting both visitors and birds into direct contact. The potential risk of bird-to-human and human-to-bird disease transmission has been addressed.

The training and working schedules of show birds are readily accepted by some animals that benefit both mentally and physically from this activity, but other birds may be stressed by this routine. This work-derived stress will influence the birds' immune systems and make them more susceptible to both infectious and non-infectious diseases. In this respect, good teamwork with trainers is important in identifying subtle changes before they become problems.

Generally speaking, show birds are individually examined two to four times per year. This examination includes a discussion with the trainers and careful inspection of the resting area where the birds live. Tests for major viral diseases are performed when a new bird is introduced to the group and then repeated as needed (see "Quarantine"). Birds are regularly screened for parasites, especially if they are free-flying animals. Blood tests, including CBC and basic biochemistries, are performed annually. Tests for chamydiosis and other bacterial diseases are performed at least twice a year, especially when direct contact with visitors occurs. Finally, a fecal screening for the presence of acid-fast bacteria is performed annually on free-flying animals.

COMMON ACCIDENTS AND ESCAPES

Zoo birds are exposed to some of the same risks as pet and aviary birds, such as poisoning, foreign body ingestion and aggression by cage mates. Situations may be unique to zoo settings.

Aggression can be inflicted by a conspecific bird or by a cage mate belonging to a different species (Fig 42.13) (see "Mixed-species Exhibits"). In the case of trauma, therapy follows emergency protocols.

When a bird escapes and flies into a dangerous animal's exhibit, it will probably be killed. If the predator is not

Fig 42.13 | A conspecific bird can inflict injury due to aggression. A bite wound on the wing of a Humboldt penguin (*Spheniscus humboldti*) is shown.

dangerous to humans (eg, small felids or canids), the bird can be netted and removed. In any other case, measures should be taken to anesthetize the predator and avoid further escape of the bird by putting a net in front of the hiding place before attempting to rescue it or being ready with a water hose to soak the bird's feathers to prevent further escape.

VETERINARIANS AND BIRD CONSERVATION

It is believed that a natural rate for extinction is about one species every 100 years. But since 1800, more than 100 bird species have become extinct, which is 50 times higher than the natural rate. Zoo veterinarians must become more involved in bird conservation programs, to prevent disease and other factors from contributing to species extinction (Fig 42.14).

Veterinarians' contributions to conservation programs can also include clinical care for individuals of highly endangered species (the highest standard veterinary care

Fig 42.14 | Spix macaws (*Cyanopsitta spixii*) are the most emblematic endangered parrot species.

must be provided) and the design and implementation of breeding and release programs.

Domestically bred birds must be fully evaluated for diseases prior to becoming part of a reintroduction program. A health check for psittacines might include the following: physical examination, complete blood count analysis, fecal parasitology, cloacal and choanal cultures, radiographs and endoscopy (biopsy) as well as testing for avian influenza, circovirus, paramyxovirus, herpesvirus, *Chlamydophila*, adenovirus and avian tuberculosis.

The veterinarian may lend his or her expertise to the release program and subsequent monitoring and handling of the subject birds.

^{*}Provided by University of Miami Avian and Wildlife Laboratory: RBC and WBC count by Unopette method from blood collected in EDTA; Spun HCT; Diff based on 100-cell count using smear made at the time of sample acquisition.

Appendix II. Avian Hematologic Reference Ranges for Clinically Normal Psittacines**

In an attempt to establish ranges for clinically normal birds of various psittacine species, the following criteria were used to determine the acceptability of individual values for incorporation into the following statistics:

- 1) The bird was presented for a wellness examination, at which time the sample was obtained.
- 2) At least one previous CBC was performed and documented at the same hospital, utilizing the same techniques, and was also performed during a wellness examination.
- 3) No other concurrent disease was detected or treated, with the exception of behavioral concerns.
- 4) The total WBC did not vary more than 25% between the two values.

Determination	African greys	Amazon sp.	Budgerigars	Cockatiels	Umbrella cockatoos	Aratinga conures	Eclectus parrots
	(n = 150)	(n = 150)	(n = 50)	(n = 200)	(n = 100)	(n = 50)	(n = 25)
WBC x 10 ³ /μl	8-11	7.5-12.5	2.5-6.5	4.0-8.8	7-11.5	7.0-11.7	7.0-11.8
PCV (%)	42-50	44-49	42-53	45-57	38-48	42-49	41-49

Determination	Lovebirds	Macaws	Pionus sp.	Quaker (monk) parakeets	Senegal parrots
	(n = 25)	(n = 100)	(n = 25)	(n = 50)	(n = 25)
WBC x 10 ³ /μl	4.5-9.0	8.5-15.5	7.0-11.5	5.5-12.5	6.5-12
PCV (%)	39-51	39-52	44-51	38-48	37-48

^{**} Compiled 1989-2001 by Teresa L. Lightfoot, DVM, Dipl ABVP-Avian: All calculations were done using the Eosinophil Unopette method; an average of the total WBC counts for the two or more CBCs that were performed was used to develop the above ranges.
